^{36}Cl production in rocks is complex and dominated by multiple production pathways at distinct energies. A particular problem is the production via natural chlorine, in rocks. This problem is reflected in the large inconsistencies of published production rates, which can differ by up to a factor of 2 (Phillips et al., 1996; Stone et al., 1996; Swanson, 1996; Swanson and Caffee, 2001). One promising way to reduce the natural chlorine background is to use mineral separates (Schimmelpfennig et al., 2009; Stone et al., 1996). Schimmelpfennig et al. (2009) also report that partial dissolution of 10–20% of the mineral separates prior to the total digestion can eliminate the natural chlorine almost completely. The ^{36}Cl tool holds large potential due to the combination of using a relatively simple chemical extraction procedure on whole-rock samples and a wide age range allowing dating of surfaces as young as several hundred years up to about 1 My. However, more methodological work is needed to improve the understanding of production rate systematics and potential problems with water mobilization of ^{36}Cl by weathering processes.

Production of Cosmogenic Nuclides in Terrestrial Rocks

As mentioned above, the rapid increase in applications of TCN methods is paralleled by a better understanding of the complexity of TCN production physics. In this section, we will briefly present these new findings impacting the TCN production systematics and their scaling with altitude and latitude, as well as recently published temporal corrections for TCN

production rates, such as corrections for geomagnetic field variations or long-term solar modulations.

Calculation of an absolute surface exposure age using TCNs at a given location on Earth requires the knowledge of the local TCN production rate through time. Time-integrated TCN production rates are estimated by (i) measuring the cosmogenic nuclide concentrations in samples from surfaces of well-constrained exposure histories or (ii) measuring the cosmogenic radionuclide concentration of an essentially uneroded surface that is old enough for the radionuclide concentration to approach saturation/secular equilibrium (i.e., a steady state between production and decay – typically 4–5 half-lives). There are relatively few such sites, however; hence, estimating the TCN production rate at a given study typically relies on scaling the production rates from the calibration locations with theoretical and empirical models of cosmic ray flux variation in time and space. Production rates are typically referenced to a hypothetical location at sea level and high geomagnetic latitude (SLHL) as a basis for comparison. Such reference production rates depend on the calibration site values as well as the particular scaling model used – i.e., values calculated with a given set of scaling parameters are not generally comparable to those calculated with another set.

TCN research in the late twentieth century relied primarily on the relatively simple production rate scaling model of Lal (1991). However, the years 2000–2005 yielded several alternative models of generally increasing complexity, in attempts to better understand the spatial and temporal variations in TCN production rates around the globe. Unfortunately, the increased complexity also yielded a corresponding increase in confusion among the user community, as it was very difficult to compare the predictions of each model directly in a consistent framework. To remedy this situation, the CRONUS-Earth project developed a set of online calculators for exposure ages and erosion rates that provide results for each published scaling model, based on an internally consistent geomagnetic and atmospheric framework using a common geochemical standardization for each nuclide (Balco et al., 2008; Goehring et al., 2010). These calculators provide users with an easy way

to compare large numbers of measurements made at different times, from different studies, in different locations. For example, they have enabled new paleoclimatic interpretations from multiple large datasets of TCN measurements (e.g., Owen et al., 2008).

Table 1 gives an overview of the recently published production rates for the TCNs ^3He , ^{21}Ne , ^{38}Ar , ^{14}C , and ^{10}Be . This table is meant to be a complementary addition to Table 4 in the review by Gosse and Phillips (2001). The timescale of SED currently ranges from a few 100 years (Stone et al., 2003a) to several tens of My (Dunai et al., 2005; Margerison et al., 2005; Schäfer et al., 1999), and the variety of lithologies that can be cosmogenically dated by various TCNs is steadily growing. Despite the numerous experiments, the production rates of TCNs on the Earth's surface and their variation in time and space represented the biggest remaining uncertainties of the method. The CRONUS-Earth and CRONUS-EU initiatives have made great strides in reducing these uncertainties.

For example, a major advance arising from the CRONUS-Earth project (and other studies) is a more precise and accurate estimate of the global ^{10}Be production rate. The greatly reduced scatter over previously published datasets (Balco et al., 2008) has resulted from careful attention to calibration site selection and independent age control, at sites spanning a range of altitudes and latitudes, as well as improvements in geochemical processing and accelerator mass spectrometry (AMS) measurement techniques. This new generation of calibration sites includes shoreline features associated with Pleistocene Lake Bonneville, Utah, Late Glacial landslide and moraine deposits in northwestern Scotland, recessional moraines in the north-eastern United States (a subset of those sampled in Balco et al. (2009)), Late Glacial deposits in Norway and near the Quelccaya ice cap in Peru, a particularly well-dated debris flow deposit in New Zealand (Putnam et al., 2010), and well-dated deposits in Patagonia (Kaplan et al., 2011) and Greenland (Briner et al., 2012). This, in turn, has allowed for previously unattainable temporal resolution in SED studies using ^{10}Be (e.g., Schaefer et al., 2009). Another key milestone in ^{10}Be applications has been the recent convergence of ^{10}Be half-life estimates (Chmeleff et al., 2010; Korschinek et al., 2010; Nishizumi et al., 2007), resolving a longstanding controversy.

Production of *in situ* cosmogenic nuclides in near-surface rocks is complex, as TCN production is a multiparameter function of the cosmic ray flux at the Earth's surface. Variations in this flux are consequences of (i) variations in the primary galactic cosmic ray flux, (ii) solar modulation of the GCR flux, (iii) changes in atmospheric shielding, and (iv) variations in the intensity and configuration of the Earth's magnetic field. While the low-frequency variation (i) is of minor importance for the application of TCN on timescales of 10^3 – 10^6 years, the other variations have to be considered. This led to a number of studies designed to characterize the various effects. The online CRONUS calculators (Balco et al., 2008; Goehring et al., 2010) each incorporate the latest advances in our understanding of these variations.

Geomagnetic Variation and TCN Production

There are several recent studies investigating the impact of geomagnetic variations in intensity and configuration on the

TCN production on the Earth's surface (Desilets and Zreda, 2003; Dunai, 2000; Gosse and Phillips, 2001; Masarik et al., 2001; Pigati and Lifton, 2004). While each predicts somewhat different impacts, the CRONUS online calculators utilize a common geomagnetic framework based largely on the model of Lifton et al. (2008), which captures the Holocene effects on TCN production of time-dependent spherical harmonic models developed by Korte and Constable (2005) and subsequent studies (Korte et al., 2009).

Solar Modulation of TCN Production

A recent study by Lifton et al. (2005) introduced correction factors for millennial-scale solar modulation of TCN production rates based on model sunspot numbers over the last 11.4 ka. They find effects on spallogenic nucleon scaling factors for SLHL of up to 10%, supporting the view that long-term solar modulation must be included in secondary cosmic ray scaling procedures.

Changes in Atmospheric Shielding

Stone (2000) introduced the effects of regional air pressure regimes different from the standard atmosphere air pressure. The biggest changes are in Antarctica, where air pressure is about 25 hPa lower on average than elsewhere, resulting in up to 30% higher production rates. This paper has also published a map of global correction factors relative to standard atmospheric values, which should be used in all TCN studies and which are included in the online CRONUS calculators. The influence of variations in the local air pressure regime during glacial periods towards lower air pressure was recently suggested by Ackert et al. (2003) as an explanation for their relatively high ^3He production rates constrained from $^{39}\text{Ar}/^{40}\text{Ar}$ -dated lava some 70 and 110 ka in age, and by Licciardi et al. (2006) in a study calibrating ^3He production rates in Iceland.

Outlook

This article focuses on the most recent progress in the method of cosmogenic surface exposure dating over the last several years, highlighting the rapid progress in the field. Cosmogenic nuclide surface exposure dating has fundamentally changed our perspectives on quantifying Earth surface processes. However, prior to 2005, controversies about TCN production systematics threatened to limit the range of potential applications. The multidisciplinary CRONUS-Earth and CRONUS-EU projects were designed to improve significantly the accuracy and reliability of TCN science while making the required production-rate systematics easier to understand and apply for the broader user community. CRONUS-Earth is winding down, but it has achieved much toward its goal of a robust foundation for quantitative surficial processes and Quaternary geologic science with reliably defined uncertainties. A particular success has been the production rate of the TCN workhorse, namely, ^{10}Be , which is now known to be better than 10% globally, and which appears to be approximately 10% lower than previously thought. Tighter constraints on ^{36}Cl production are another

positive outcome. Finally, a better understanding of scaling systematics is within reach as a result of this work. While it remains the prime tool for modern Earth sciences research, future progress in this field can expand TCN applications to disciplines such as archaeology.

Introduction

Nuclear interactions occur everywhere in the universe as natural radiations are present everywhere. The types of interactions and their magnitude show a wide variety as would be expected. Nuclear interactions, particularly the inelastic variety, in which energy transfers occur between the incident particle and the target, have been increasingly used in the past few decades to study the history of evolution of planetary matter. Considering the topics covered in this encyclopedia, the emphasis is on nuclear interactions caused by cosmic radiation in Earth's atmosphere and in upper layers of the lithosphere, with a view to use interaction products as tracers for studying geomorphic processes. It must be pointed out here that this is a field that has now become accessible to quantitative modeling as a result of the recent advances that have made it possible to measure the ultralow concentrations of nuclear products arising from nuclear interactions in surficial and deep-seated materials (Gosse and Phillips, 2001; Lal, 1988a, 1991; Tuniz et al., 1998). Prior to this development, only sketchy information based on indirect assessments, such as coatings on surfaces and thermoluminescence, was available.

To understand the principles and uncertainties of terrestrial *in situ* cosmogenic nuclide (TCN) methods, it is necessary to appreciate the theory and experimental basis for our understanding of primary cosmic ray interactions in the atmosphere and the subsequent interactions between cosmic ray secondaries and matter. Although the theoretical framework allows fairly accurate estimations of the temporal variations in the cosmic ray flux at the top of the atmosphere for hypothetical changes in the geomagnetic field and solar activity, and although the basic features of nuclear interactions are fairly well understood, it is indeed a difficult task to accurately estimate the total rates of nuclear disintegrations and particular nuclear interaction rates giving rise to specified nuclides at different locations in the atmosphere.

Cosmic rays attenuate as they interact with mass, at a rate referred to as an interaction mean free path. Earth's atmosphere represents more than ten interaction mean free paths for the geometric nuclear interaction of nucleons (protons or neutrons) with air nuclei, about 90 g cm^{-2} . Within the lithosphere, the character of nuclear interacting particles changes dramatically, from primarily nucleons to slow and fast muons. Within the atmosphere, the total rate of nuclear disintegrations changes by a factor of 10^2 at the equator and 1.5×10^3 at the poles, between the top of the atmosphere and sea level (Lal and Peters, 1967). It is quite manifest that the atmosphere imposes a heavy demand on any nuclear systematics used to treat the nuclear cascade development. Nuclear interactions are complex, with emission of different particles over a wide range of energies, and with a complex angular distribution (with respect to the incident particle). This requires parametrization of

secondary particle emission characteristics as a function of energy for MeV to GeV energies. As an example, even if one makes an error of 10% in the assignment of the value of one of the relevant parameters, this would lead to an error of $>100\%$ in taking the nucleonic cascade to sea level (Lal, 2000). Even a 10% error in the assignment of geometric nuclear interaction cross-section (the probability of interaction) produces the same effect. The propagation of the generating component of nucleons through the atmosphere depends critically on the inelasticity parameter, which fortunately does not show a strong energy dependence. The observations of cosmic ray neutrons show that at low latitudes the secondary nucleonic component at atmospheric depths greater than 200 g cm^{-2} is appreciably harder than at the poles, which is not unexpected because of the much harder energy spectrum of the primary radiation incident at the equator (protons of $E > 14 \text{ GeV}$ and He nuclei above 6.6 GeV/n). The absorption mean free paths lie in the range of $220\text{--}160 \text{ g cm}^{-2}$ between the equator and the poles. A 10% uncertainty in the mean free paths corresponds to a 35% uncertainty in scaling factors between sea level at 60° and 3 km at the equator.

There is a need for accurate estimates of production rates of nuclides in the atmosphere and at underground depths. Even if the total nuclear disintegration rates can be estimated, it is not generally feasible to make accurate estimations of nuclide production rates. One of the difficulties, in particular, is a lack of knowledge of partial cross-sections for the formation of nuclides in different target elements as a function of neutron energy, because in the atmosphere, neutrons are the principal producers of nuclear interactions.

It is very difficult to depend entirely on theory to accomplish the tasks. One has to employ suitable 'process normalization' techniques, treating finite size chunks of matter as black boxes, without going into details of the interaction. In this treatment, as an example, one assumes that the more energetic component of nucleons is absorbed following certain observed features in high-energy interactions, whereby, after an interaction, the incident nucleon continues with an appreciable energy. The absorption of an incident nucleon (neutron or proton) in matter is then governed by simple absorption rules, again guided by experimental data. It further follows that within a few interaction mean free paths in the target (atmosphere or rock), there would exist certain relationships between the propagating nucleon components in different energy bands, with near-equilibrium between high- and low-energy nucleons. In fact, accepting this makes it possible to make very accurate predictions of fluxes of secondary nucleons in a target.

However, it must be mentioned that apparently some numerical codes are able to predict the buildup of nucleonic cascades in the atmosphere, and sometimes they also predict the partial cross-sections for the formation of different nuclides as a function of energy (Masarik and Reedy, 1995). However,

the codes must also rest heavily on normalization techniques as data are simply not available to treat in any detail the processes that occur in nuclear interactions, as mentioned above.

A practical approach, therefore, is to consider the dynamics of nuclide production theoretically and to obtain absolute nuclide production rates wherever possible by exposing suitable targets to cosmic radiation at different altitudes and latitudes (Lal et al., 1960), as was first shown in the case of radionuclides of half-lives <3 months. With the development of the accelerator mass spectrometry technique, it is now possible to extend this method to long half-life radionuclides (cf. Nishiizumi et al., 1996). Currently utilized production rates of TCN have therefore been empirically based on measurements of the isotope for targets as short as a year to targets as long as tens of thousands of years. The longer duration experiments make use of geological surfaces with exposure ages that have been determined independently (e.g., radiocarbon-dated lava).

Two approaches are currently being used in applications of the cosmogenic nuclides as tracers for production: one to determine the scaling factors for neutrons of different energies at different altitudes and latitudes, and the other to determine the absolute production rates of a nuclide in the atmosphere or in targets exposed in the atmosphere at a few sites. The latter is very necessary, partly because of lack of data on partial cross-sections for formation of nuclides from different target elements. Additionally, semiempirical approaches have to be used to estimate nuclide production within rocks of different sizes exposed at different elevations in the atmosphere (Lal and Chen, 2005; Masarik and Wieler, 2003).

Cosmic Radiation: The Omnipresent Energetic Nuclear Radiation

Among the four principal radiations, which are present everywhere in the universe, electromagnetic radiation, cosmic radiation, neutrinos, and gravitational radiation, the former two occupy a large band in energy, >15 orders of magnitude. By this fact alone, they serve as windows to the universe to map the distribution of gases, dust, and different forms of matter including stars. Cosmic radiation, discovered in 1912 by Victor Hess by carrying his charged-particle detector instrument to an altitude of 17 500 ft in a gondola, consists of nuclei of elements in the periodic table with energies of a few electron volts to $>10^{20}$ eV. In cosmic ray physics, it is customary to measure nuclear particle energies in electron volts. Further, because one must often deal with nuclear matter moving with speeds comparable to the speed of light, it becomes necessary to use relativistic equations derived from Lorentz transformations. The magnitude of the electron volt and the relativistic relations between particle's mass, momentum, and energy are briefly outlined in Appendix A.

As discussed below, most of the cosmic ray flux incident at the Earth lies in the region of a few thousand MeV. Since the binding energy of nucleons (neutrons or protons) in matter also lie in the range of few MeV, the cosmic ray particles are capable of fragmenting nuclei with which they interact. Indeed, they produce appreciable nuclear transformations in the Earth's atmosphere and even in the lithosphere down to great depths. This results in production of new forms of nuclei, some not initially present in the targets. In contrast, the

electromagnetic radiation, which interacts very weakly with matter by virtue of its coulomb field, does not produce any appreciable changes in the nuclear composition of matter.

In this article, we discuss the salient features of cosmic radiation, their composition and energy spectra, development of the secondary cosmic ray beam in the atmosphere and the lithosphere, and production of nuclides in this process by the principal nuclear active particles. The incident cosmic ray flux at the top of the atmosphere is latitude dependent since it is strongly modulated by (1) the Earth's geomagnetic field and (2) solar plasma. These modulations show temporal variability because both geomagnetic field and solar activity are variable. We explicitly consider the nature of this variability.

Composition and Energy Spectrum of Cosmic Rays

'Cosmic rays' are composed of ordinary forms of matter accelerated by electromagnetic processes in certain flares in stars, and by shock processes in explosions of supernovas to relativistic energies. (The term cosmic radiation was originally adopted to reflect our lack of knowledge of their acceleration mechanisms and also the stellar sources primarily responsible for their acceleration. It remains today as the term of choice because of the multiplicity of its sources in the universe, from stars to supernovas.)

Although cosmic rays are accelerated in several astrophysical settings, the principal source of energy for galactic cosmic ray (GCR) acceleration seems to be shock waves driven by the explosions of supernovas (see Higdon et al., 1998; Ramaty et al., 1998; and references therein). Most (80–90%) of the galactic supernovas are type II and Ib/C (core collapses of massive O and B stars). Since the average supernova energy release is about 10^{50} erg, and their frequency is ~ 3 per century, the average cosmic ray power, 10^{41} erg s $^{-1}$, needed to maintain the level of 'galactic' cosmic rays is met by supernovas.

As would be expected, the cosmic ray beam is composed of fast nuclei up to relativistic energies, completely stripped of their electrons in the early stages of acceleration. Since hydrogen is the most abundant element in the universe, most of the flux is comprised of protons. Next in abundance are He, C, N, O, and heavier nuclei. Li, Be, B ions are rare in the universe. Their presence in the cosmic ray beam arises primarily due to nuclear interactions of heavier nuclei.

The wide range of cosmic ray energies requires that their energy spectra be described in terms of a power law function in kinetic energy, E_k , as differential or integral forms:

$$\frac{dn}{dE_k} = j(E_k) \quad [1]$$

$$N(> E_k) = \int_{E_k} j(E_k) dE_k \quad [2]$$

E_k is defined as kinetic energy of the particle. In the case of complex nuclei, such as He and heavier nuclei (C, N, O, Si, Fe, etc.), it is often defined as kinetic energy per nucleon. A typical form of $j(E_k)$ over a wide range of energies is: $(a + E_k)^{-\Gamma}$, except at low energies, where it is of the form: $(a + E_k)^{-\Gamma}$, where a is a constant. At kinetic energies >3 GeV, the value of Γ is ~ 2.5 . For further details, see Peters (1958), Simpson (1983, 1992), and Ziegler (1998).

Primary GCR Energy Spectra and its Modulation by Solar Plasma

The differential energy spectra of H, He, C, and Fe nuclei in the energy region $10\text{--}10^4$ MeV per nucleon are shown in **Figure 1**, obtained using instruments flown in a large number of balloon flights at the top of the atmosphere (Simpson, 1992). The scatter in the measured data, taken at different periods, arises from varying modulation of the cosmic ray beam by the solar plasma. The primary GCR flux incident at the top of Earth's atmosphere is anticorrelated with solar activity (with some phase lag). See Gleeson and Axford (1968) for a convection-diffusion theoretical framework for the transport of GCR particles through the heliosphere, and see Castagnoli and Lal (1980) and Papini et al. (1996) for the essential features of the experimental data on solar modulation of primary cosmic ray flux.

In terms of the solar modulation formulism (Gleeson and Axford, 1968), the effective change in the energy of a charged particle moving from a point P on the boundary along a dynamical trajectory to an interior point Q is $Ze\phi$, irrespective

of its path to Q. If the measured kinetic energy of a charged particle at Q is E_k per nucleon, then it follows (Randall and Van Allen, 1986) that its kinetic energy per nucleon at P must have been $(E_k + Ze\phi)$. As shown by Randall and Van Allen (1986), this leads to the following simple equation relating differential fluxes at points P and Q:

$$\frac{j_Q(T)}{T(T + 2mc^2)} = \frac{j_P(T + (Ze\phi/A))}{(T + (Ze\phi/A))(T + Ze\phi/A + 2mc^2)} \quad [3]$$

In eqn [3], A is the mass number, T is defined as the kinetic energy per nucleon, the total kinetic energy being AE_k . If the point P is taken at the heliosphere boundary, and the point Q at 1 AU, then the charged particle is modulated through a potential difference of ϕ MeV per nucleon.

For more than four decades, the solar modulation of cosmic ray flux has been studied using satellites/spacecraft in orbit around Earth, and more recently on deep space probes. The range of observed variations in the modulated near-Earth differential flux of GCR protons until the late 1970s is shown in **Figure 2** for protons, as described by different curves designated by the modulation parameter, ϕ (Castagnoli and Lal, 1980; Randall and Van Allen, 1986). The hypothetical curve, $\phi=0$, corresponds to the predicted shape of the interstellar GCR proton flux, that is, the GCR flux outside the outer heliosphere. Information about near-Earth changes in flux have come largely from the charged-particle monitoring experiment aboard the IMP8 satellite since 1973. For a recent summary of these data, reference is made to Simunac and Armstrong (2004).

Our knowledge of modulation of GCR through the outer heliosphere comes from deep space probes (Fuji and McDonald, 1997; Lockwood and Webber, 1995) which transmitted *in situ* cosmic ray data up to distances of more than 70 AU (Pioneers 10 and 11, Voyagers 1 and 2). In **Figure 3** are plotted the results of measurements of time variations in the differential particle fluxes of H ions of 130–225 MeV and He ions of 10–21 and 180–450 MeV/n kinetic energies (Fuji and McDonald, 1997), at distances of up to ~ 60 AU during 1972–95. In the same figure, the measured changes in the counting rates of the neutron monitor at Climax are also presented. Finally, **Figure 4** shows the data on energy spectra of protons measured by Pioneer 10 and Voyager 2 spacecrafts from 1978 to 1992 for GCR protons of >70 MeV kinetic energy and corresponding near-Earth fluxes based on IMP satellite (Lockwood and Webber, 1995). The radial distances of Pioneer 10 and Voyager 2 were ~ 60 and 40 AU, respectively, in 1992.

Figures 2–4 show a consistent behavior of modulation of cosmic ray flux at radial distances of 1–60 AU space in the heliosphere, corresponding to modulation parameter, ϕ values ranging between ~ 350 and 1300 MeV/n, inversely correlated with solar activity (often defined using the Zurich sunspot numbers). During sustained solar minimum periods, as during the Maunder Minimum, the value of ϕ may have been ~ 100 MeV/n (Castagnoli and Lal, 1980).

Figure 1 The energy spectra of elements in cosmic rays (from top: H, He, C, and Fe) measured near Earth. The solid curve shows the hydrogen spectrum extrapolated for interstellar space, for no solar modulation. Solar Cosmic Ray Energy Spectra

The energy spectra of energetic particles accelerated during certain solar flares are often represented as a power law (see Aschwanden, 2002; Lal, 1972, 1988b):

Figure 2 Estimated proton spectra for different solar modulation intensities as defined by ϕ and guided by observed proton spectra during different years (see text). Cosmic ray fluxes for different ϕ values are described well by eqn [3].

Figure 3 Time histories of the 26-day average galactic cosmic ray intensities of H and He, and of thermal neutrons measured at Climax. Reproduced from Fuji Z and McDonald FB (1997) Radial intensity gradients of galactic cosmic rays (1972–1995) in the heliosphere. *Journal of Geophysical Research* 102(A11): 24201–24208.

Figure 4 Observed cosmic ray fluxes of protons of kinetic energy >70 MeV by Pioneer 10 and Voyager 2 spacecrafts from 1978 to 1992 for GCR protons of 70 MeV kinetic energy, and near-Earth fluxes based on IMP satellite. The radial distances of Pioneer 10 and Voyager 2 were ~ 60 and 40 AU, respectively, in 1992. Redrawn from Lockwood JA and Webber WR (1995) An estimate of the location of modulation boundary for $E > 70$ MeV galactic cosmic rays using voyager and pioneer spacecraft data. *The Astrophysical Journal* 442: 852–860.

$$\frac{dn}{dE_k} = \text{constant} \times E_k^{-\Gamma} \quad [4]$$

However, the value of Γ changes rapidly with energy in the interval (1:100) MeV/n; it usually lies between 2 and 4. A much better fit is the exponential rigidity spectrum:

$$\frac{dn(R)}{dR} = \text{constant} \cdot e^{(-R/R_0)} \quad [5]$$

where R is the rigidity (Appendix A) and R_0 is a constant for the time-averaged spectrum of the solar particles in a flare event. The value of R_0 ranges between 50 and 200 MV in most flares (Lal, 1988b).

The solar cosmic ray (SCR) energy spectra are very soft compared to the GCR spectra, as can be seen from Figure 5, which presents the range of temporally observed variations in the GCR and SCR fluxes (Lal, 1988b). A quiet-time GCR spectrum in Figure 5 implies that the spectrum was not affected by SCR protons at the time of measurement.

As can be seen from Figure 5, the energy of the bulk of SCR proton flux is >100 MeV. The range of a proton of 100 MeV in air is <10 g cm^{-2} (Ziegler, 2004), only about 10% of an interaction mean free path for its nuclear interaction (Appendix B, Figure 6). Because of the geomagnetic cutoff (Appendix C), SCR protons are only incident at geomagnetic latitudes $>80^\circ$. Further, they are lost by nuclear interactions in the upper atmosphere. Any neutrons produced by them would however be slowed down reaching greater depths in the atmosphere and would mostly give rise to ^{14}C by getting captured in ^{14}N nucleus.

In view of the above, the principal effect of SCR is to produce ^{14}C in the atmosphere. Even here, detailed calculations by Castagnoli and Lal (1980) show that the SCR production of ^{14}C is generally negligible compared to its production

by GCR, but significant amounts could be produced in very large SCR events in some flares.

Development of the Secondary Particles of the Cosmic Radiation in the Earth's Atmosphere

A great deal is known about the basic processes which occur when energetic H, He, and heavier nuclei interact with matter, based on the early observations of nuclear interactions, and disintegrations of unstable particles as observed in photographic nuclear emulsions (Powell, 1959) and subsequent observations of high-energy particles accelerated up to ~ 30 GeV in particle accelerators. In Figures 7 and 8, we present examples of nuclear interactions of energetic protons and in Figure 9, an example of decay of an unstable particle (figures taken from Powell et al. (1959)). Several examples of first observations of interactions of multiply charged particles can be found in Bradt and Peters (1950).

A detailed description of the salient features of nuclear interactions is given by Lal and Peters (1967). We present here some of the important aspects of the propagation of the cosmic rays through the atmosphere.

The secondary cosmic ray phenomena are quite complex depending on the energy of the primary cosmic ray particle. Considering a group of interactions of an ensemble of cosmic ray primaries, the following is a good description of the secondary particles. The first-generation secondary particles are nucleons, pions, and a variety of unstable (elementary) particles. The nucleons and charged pions produce further nuclear interactions. Because of the low density of the atmosphere, most charged pions decay to muons before they interact. Neutral pions decay to photons which give rise to soft cascades (electrons and positrons). For properties of the elementary

particles, see [Review of Particle Physics \(2004\)](#). We note here that the elementary particles are classified under the headings hadrons and leptons. Mesons (π and K) are bosons with spin 0, while nucleons, hyperons, leptons, and neutrinos are fermions

Figure 5 Observed solar modulated GCR fluxes of protons during different years (the last two digits of the year are shown), and the inferred local interstellar GCR proton spectrum are shown alongside solar cosmic ray (SCR) proton spectra. The time-averaged SCR proton spectra are shown for the solar cycles 19, 20, and 21 (1954–86) along with the long-term average spectrum based on observations of lunar rocks. Reproduced from Lal D (1988) Temporal variations of low energy cosmic ray protons on decadal and million year time scales: Implications of their origin. *Astrophysics and Space Science* 144: 337–346.

with spin 1/2. Among leptons are electrons, positrons, muon, and tauon. Note that muon is not called a meson because it is not a boson.

The fluxes of various cosmic ray secondary particles (nucleons, mesons, and electrons) change with depth in the atmosphere at geomagnetic latitude 45° and longitude 80° west (Lal and Peters, 1967; Peters, 1958; Figure 10). In this figure, the γ -ray flux is not shown; the photon:electron ratio is about unity at sea level and increases to a value of about 2 at 3500 m altitude. For approximate rates of nuclear disintegrations by nucleons and mesons, see Lal (1988a). It is seen from Figure 10 that at atmospheric depths of ~ 150 – 200 g cm^{-2} , there occurs a transition in the fluxes of nucleons, mesons, and electrons when these fluxes build up to a maxima due to nuclear cascades. At depths exceeding 200 g cm^{-2} , nucleons in different energy regions reach an equilibrium, the nucleonic cascade being sustained by high-energy nucleons of $E_k \geq 3 \text{ GeV}$.

Very detailed information on the generation of the secondary component in nuclear interactions became available from observations of secondary particles in nuclear emulsions exposed at different altitudes and latitudes in the atmosphere. From measurements of grain densities of tracks in nuclear interactions, Camerini et al. (1949) deduced the energy spectra of secondary particles produced in these interactions. These data are very useful for estimating the development of secondary cosmic ray particles in the atmosphere, and nuclear disintegration rates (Lal, 1988a; Powell et al., 1959; Rossi, 1952). From these data, Rossi (1952) has deduced the relative energy spectra of neutrons and protons at a depth of 700 g cm^{-2} in the atmosphere. This is in good agreement with the direct measurements of proton spectra, and the corresponding neutron fluxes based on the observed rates of nuclear disintegrations in nuclear emulsions by neutrons and protons (Lal, 1958; Lal and Peters, 1967). In Figure 11, we show the differential spectra of protons calculated in this way along with the measured proton spectrum at geomagnetic latitude 50° and atmospheric depth, 680 g cm^{-2} . The nuclear emulsion data provide the most direct means of obtaining neutron spectra in the atmosphere for kinetic energies in the MeV–GeV region; it is very difficult to obtain reliable neutron spectra using detectors, as was attempted by Hess et al. (1959).

It is seen from Figure 11 that the fluxes of protons and neutrons are about the same at $E_k \geq 1000 \text{ MeV}$, but proton fluxes are progressively smaller at lower energies than those of neutrons. They are produced in about the same numbers in nuclear interactions. However, protons produce fewer interactions as low-energy protons are brought to rest by ionization

Figure 6 Coordinate system used in defining arrival directions of cosmic ray particles.

Figure 7 An example of a high-energy cosmic ray proton producing a nuclear interaction with a silver or bromine nucleus in the photographic nuclear emulsion. The incident proton track (shown by an arrow on the top) and other similarly appearing 'gray tracks' (five marked S for secondary) are due to energetic particles (protons and unstable particles) of low ionization rate. The 16 darker tracks, on the other hand, are due to slow protons and heavier ionization rates. Reproduced from Powell CF, Fowler PH, and Perkins DH (1959) *The Study of Elementary Particles by the Photographic Method*, p. 669. New York: Pergamon.

Figure 8 Example of an energetic nuclear interaction produced by a cosmic ray proton (estimated to be of ~ 30 GeV kinetic energy) with a silver or bromine nucleus in the photographic nuclear emulsion. The incident proton track is shown by an arrow labeled P on the top. Nine tracks of energetic mesons (gray tracks) and 22 darker tracks of different ionization rates are seen. Reproduced from Powell CF, Fowler PH, and Perkins DH (1959) *The Study of Elementary Particles by the Photographic Method*, p. 669. New York: Pergamon.

losses before they can interact. The ranges of a proton of 100, 500, and 1000 MeV in air are ~ 10 , 150, and 500 g cm^{-2} , respectively (Ziegler, 2004). The nuclear geometric and absorption mean free paths of nucleons are ~ 90 and 160 g cm^{-2} , respectively (Appendix B).

In the atmosphere, neutrons produce 90% of the nuclear interactions. The contribution of γ -radiation to nuclear interactions is about 5% at atmospheric depth of $\sim 200 \text{ g cm}^{-2}$ where its flux reaches a maximum (Figure 10); however, it can be neglected when considering the atmosphere as a whole. The contribution of muons to nuclear interactions becomes important below the atmosphere. In the following section, we present nuclear disintegration rates in the atmosphere and in the rocks and sediment of the upper tens of meters realm in the lithosphere.

Nuclear Disintegration Rates in the Atmosphere

The total rate of nuclear disintegrations in the atmosphere have been estimated, based on observed rates of nuclear disintegrations in nuclear emulsions and cloud chambers at different altitudes and latitudes, the measured low-energy neutron fluxes using neutron monitors located at several sites, and neutron fluxes measured in the atmosphere at different altitudes and

latitudes using boron trifluoride counters flown by balloons (Lal and Peters, 1967). In the upper atmosphere ($< 200 \text{ g cm}^{-2}$ depth), low-energy neutrons are not in equilibrium with fast nucleons. Furthermore, in this region, slow neutrons escape from the atmosphere. Even in the equilibrium region of the atmosphere ($> 200 \text{ g cm}^{-2}$ depth), only nucleons of $E_k < 400 \text{ MeV}$ are in equilibrium with slow neutrons. Taking into account all these factors, the total rates of nuclear disintegrations produced in the atmosphere with energy release $\geq 40 \text{ MeV}$ have been estimated (Lal, 1958, 1988c; Lal and Peters, 1967), as shown in Figure 12. These rates refer to a period of high solar activity since the neutron data come from observations during 1948–49.

The appreciable differences in the rate of nuclear interactions with latitude arise due to the modulation of cosmic ray flux by the Earth's geomagnetic field. As examples, the minimum kinetic energy which a vertically incident proton should have at geomagnetic latitudes of 0° , 30° , 60° , and 80° are, respectively, 14.0, 7.49, 0.384, and 0.0001 GeV (Appendix C).

The effect of geomagnetic field changes on nuclear disintegration rates can be seen from Figure 13, which shows the global mean nuclear disintegration rate as a function of geomagnetic field strength (relative to present field) and solar modulation parameter, ϕ .

Figure 9 Example of decay of a τ -meson into three π -mesons in photographic nuclear emulsion. The darker wiggly track is due to τ -meson which comes to rest by ionization loss at the point P and decays giving rise to three π -meson tracks. Reproduced from Powell CF, Fowler PH, and Perkins DH (1959) *The Study of Elementary Particles by the Photographic Method*, p. 669. New York: Pergamon.

The minimum kinetic energy of a vertically incident proton at geomagnetic latitudes of 0° , 10° , 20° , 30° , 40° , 50° , 60° , 70° , 80° , and 90° are, respectively, 14.0, 13.1, 10.7, 7.49, 4.28, 1.77, 0.384, 0.02, 0.0001, and 0 GeV (Appendix C). The differential primary fluxes at these energies are given in Figure 2 for different states of solar modulation.

Temporal Variations in Cosmic Ray Nuclear Disintegration Rates

The incident cosmic ray flux at the top of the atmosphere is latitude dependent since it is strongly modulated by (1) the Earth's geomagnetic field and (2) solar plasma. Temporal variations in these parameters are therefore the two principal expected causes of changes in nuclear disintegration rates on the Earth. We do not expect to see any appreciable changes in the GCR intensity, except if a supernova explosion occurs nearby. This is supported by direct measurements of long-term constancy of cosmic radiation based on meteoritic evidence (Arnold et al., 1961), and the long galactic confinement of cosmic rays in the galaxy (~ 20 Ma; Simpson and Connell, 1998), combined with the fact that cosmic rays are replenished continually by supernovas whose frequency is quite high (~ 3 per century).

Temporal variations in nuclear disintegration rates due to changes in solar activity would depend strongly on altitude

Figure 10 Composition of cosmic ray secondaries as a function of atmospheric depth at geomagnetic latitude 45° and longitude 80° west. The symbols in the figure are: HN (multiply charged (heavy) nuclei); FN (fast neutrons of $E_k \geq 3$ GeV); FP (fast protons of ≥ 3 GeV); SP (slow protons of $0.4 < E_k < 3$ GeV); FM (fast mesons of ≤ 220 MeV kinetic energy); SM (slow protons of $27 < E_k < 220$ MeV), and e ($E_k \geq 10$ MeV). Redrawn from Lal D and Peters B (1967) Cosmic ray produced radioactivity on the Earth. In: *Handbuch der Physik*, vol. 46(2), pp. 551–612. Berlin: Springer; see also Peters (1958).

Figure 11 Differential kinetic energy spectra of protons (measured) and neutrons (estimated; see text) in the atmosphere at geomagnetic latitude 50° and depth 680 g cm^{-2} . Figure taken from Lal D and Peters B (1967) Cosmic ray produced radioactivity on the Earth. In: *Handbuch der Physik*, vol. 46(2), pp. 551–612. Berlin: Springer.

and latitude. Since the largest solar modulation effect is on the low energies, the temporal variations would be the greatest in the polar regions at high altitudes. As an example, the magnitude of change in cosmic ray intensity at different depths in the atmosphere between 1954 (a period of low solar activity) and 1958 (a period of unusually high solar activity) is shown in **Figure 15(b)**, page 579 of Lal and Peters (1967).

The effect of geomagnetic field changes on nuclear disintegration rates can be seen from **Figure 13**, which shows the global mean nuclear disintegration rate as a function of geomagnetic field strength (relative to present field) and solar modulation parameter, ϕ .

Nuclear Disintegration Rates in the Upper Lithosphere

As can be seen from **Figure 10**, the flux of fast neutrons decreases appreciably at sea level, decreasing with an absorption mean free path of $\sim 160 \text{ g cm}^{-2}$ (Gosse and Phillips, 2001; Lal and Peters, 1967), but the flux of fast mesons remains appreciable. In the atmosphere, most of the fast π -mesons decay before interacting, giving rise to fast muons. The latter component is absorbed slowly in the atmosphere; muons lose energy primarily by ionization, *bremsstrahlung* (braking radiation), and inelastic nuclear scattering. Loss of fast muons by nuclear interactions is not significant because they interact

Figure 12 The total rate of nuclear disintegrations in the atmosphere, with energy release 40 MeV, is plotted as a function of altitude and geomagnetic latitude, in steps of 10° . Curves for different latitudes have been successively displaced along the abscissa by 1 km (based on Lal and Peters, 1967).

Figure 13 The global mean nuclear disintegration rate is plotted as a function of geomagnetic field strength, M (relative to present field, M_0) and solar modulation parameter $\phi = 100, 450$, and 1000 MeV .

with an effective (weakly energy dependent) Coulombic (photonuclear) cross-section of $\sim 3 \times 10^{-30} \text{ cm}^2$ per nucleon (cf. Heisinger et al., 2002a; Wolfendale et al., 1972). Compare this with geometric nuclear cross-sections, $\sim 4.5 \times 10^{-26} \text{ Å}^{2/3} \text{ cm}^2$ (Appendix B, eqn [B.5]). Negative muon captures by nuclei result in nuclear disintegrations, with energy release of a few tens of MeV at most. Energy release in nuclear interactions by fast muons is about an order of magnitude greater than in the capture of negative muons at rest.

Cosmic ray literature is extensive on cosmic rays underground (cf. Bhat and Ramana Murthy, 1973; Menon and Ramana Murthy, 1967). Cosmic ray muon intensities have been measured to underground depths of $\sim 3.7 \text{ km}$. In **Figure 14**, we present rates of nuclear disintegrations underground in

Figure 14 Nuclear disintegration rates due to fast neutrons and muons (fast muons and slow negative muons) in standard rock (density = 3.09 g cm^{-3} ; $Z^2/A = 6.3$). Reference is made to Lal (1987) for sources of data and the procedures used to determine the disintegration rates. Depths given are below sea level (1030 g cm^{-2}).

standard rock (density = 3.09 g cm^{-3} ; $Z^2/A = 6.3$), produced by neutrons and muons. For sources of data and the procedures used to determine the disintegration rates, reference is made to Lal (1987).

Rates of Nuclear Interactions in Targets Exposed at Different Altitudes in the Atmosphere

Thus far, we have presented rates of nuclear disintegrations in the atmosphere and in standard rock at underground depths. If a target is exposed in or at the bottom of the atmosphere, the rates of nuclear disintegrations in any mineral can be estimated. At altitudes within the atmosphere, nuclear interactions of fast muons are not important. Below, we discuss how nuclear disintegration rates for other particles can be estimated in minerals.

Fast Nucleons

The rates of nuclear disintegrations by fast nucleons in the target can be obtained by scaling the geometric cross-section according to eqn [B.5]. For a given omnidirectional cosmic ray flux, the number of interactions per gram target is proportional to the product $n\sigma$ (eqn [B.3]) (where n is the number of target atoms per g), and σ is the geometric nuclear interaction

cross-section. If, therefore, the rate of nuclear interactions due to fast neutrons is known for air, the nuclear interaction rate in the target would be the product of the nuclear reaction rate in air multiplied by a factor, f :

$$f = \left(\frac{A_{\text{target}}}{\bar{A}_{\text{atmosphere}}} \right)^{-1/3} \quad [6]$$

where $\bar{A}_{\text{atmosphere}}$ is the abundance weighted mean mass number of air, since n scales as A^{-1} and σ scales as $A^{2/3}$ (eqn [B.5]).

Slow Negative Muons

In the atmosphere, the rate of stopping negative muons, S_{μ^-} is given by:

$$S_{\mu^-} (\text{g}^{-1} \text{s}^{-1}) = 5.1 \times 10^{-6} e^{(-X/A_a)} \quad [7]$$

where X is the atmospheric depth (g cm^{-2}) and A_a is the absorption mean free path for negative muons (cf. Lal, 1988a,b,c); the value of A_a is 247 g cm^{-2} for $160 < X < 1030 \text{ g cm}^{-2}$. In light nuclei, the rate of capture of negative muons by the nucleus depends on the target mass number. Negative muons are quickly captured in the K-shell of the atom but in light nuclei a fraction of the decay occurs before they are captured by the nucleus. For details, reference is made to Figure 4 in Lal (1988b).

Figure 15 Total column production rates ($\text{cm}^{-2} \text{s}^{-1}$) of (a) ^{14}C and (b) ^{10}Be in the atmosphere are shown as a function of latitude for discrete values of the solar modulation parameter, ϕ .

Thermal Neutrons

In the atmosphere, most of the thermal neutrons are captured by N as it has the greatest abundance and highest cross-section among the atmospheric constituents. Rates of production of ^{14}C in the atmosphere during solar minimum and maximum periods observed during 1950–60 (Lingenfelter, 1963) are presented in Figures 11 and 12 in Lal and Peters (1967). From these data, one can calculate the thermal neutron fluxes within the atmosphere.

The differences in the strength of interaction of these three components of secondary radiation have been utilized to help determine the exposure ages and the erosion rates of a wide range of landforms and landscapes over a wide timescale (see Nishiizumi et al., 1993).

Rates of Production of Nuclides at Different Altitudes in the Atmosphere and at Depths in the Lithosphere

Detailed calculations of production rates of several nuclides are presented as a function of latitude and altitude by Lal and Peters (1967). The column-integrated global average production rates are also given by these authors. These estimates are based on three methods: (1) suitable (energy-dependent) normalization to nuclear disintegration rates in cases where absolute production rates are available at some point(s) in the atmosphere; (2) observed distribution of different-sized nuclear disintegrations in nuclear emulsions, and the partitioning of isotopes in nuclear spallation at different energies; and (3) partial cross-sections and the energy spectra of the nucleonic component. The first method is the most reliable; the second method fares much better than the third method because it is closest to the nuclear reaction dynamics and because the relevant cross-sections for neutrons, which produce most of the nuclides in the atmosphere, are generally few or are not available.

The latitudinal column production rates ($\text{cm}^{-2} \text{s}^{-1}$) of ^{14}C and ^{10}Be in the atmosphere are shown in Figure 15 as a function of latitude for discrete values of the solar modulation parameter, ϕ (Lal, 1988c).

At underground depths, fluxes of slow and fast muons are presented by Heisinger et al. (2002a,b), along with a large

number of cross-sections for production of a large number of nuclides from different targets up to depths of 10^5 g cm^{-2} . This is the most comprehensive summary available to date, based on cosmic ray and cross-section data. These data allow fairly detailed calculations of the production rates of the frequently measured radionuclides, ^{10}Be , ^{14}C , and ^{26}Al , by fast muons, and slow negative muons. The production of nuclides by fast neutrons is important only at depths $< 10^3 \text{ g cm}^{-2}$ (Figure 15; i.e., about 4 m of granite or 5 m of gravel).

The flux of thermal neutrons at sea level or near the atmosphere–lithosphere interface does not show a simple absorption. In fact, the flux is enhanced due to back-scattering neutrons produced in the crust/rock. Also, a depth transition occurs within the denser material in the neutron flux at depths of $< 50 \text{ g cm}^{-2}$ (Phillips et al., 2001), after which the thermal neutron flux decreases, following the absorption of the (parent) high-energy neutrons.

Rates of Production of Nuclides in Landforms Exposed at Different Altitudes in the Atmosphere and Lithosphere

The rate of production of a nuclide in a target is given by eqn [B.4]. As the rates of nuclear disintegration in the atmosphere are known, one can derive the nuclide production rates in any target using any of the three methods discussed in the previous section. In large targets, such as boulders or tors, however, one has to take into account the absorption of the secondary cosmic ray beam.

The relative nuclide production rates at a point, $P(x, y, z)$, within a body can then be obtained by integrating the following equation (Lal and Chen, 2005):

$$P(x, y, z) = \iint F(\theta, \text{surface}) \sin(\theta) \cdot e^{-\rho \vec{r}(x, y, z, \theta, \phi)/\Lambda} d\theta d\phi \quad [8]$$

where $\vec{r}(x, y, z, \theta, \phi)$ is the particular path length vector to reach the point (x, y, z) in the direction of incidence of the cosmic ray particle, θ , ϕ (see Appendix B for definitions of symbols). The parameter ρ signifies the mean density of the matrix and Λ is the mean absorption coefficient for nuclear interacting particles. A compilation of measured values of Λ

can be found in Gosse and Phillips (2001). From studies of neutrons and nuclear interactions in the equilibrium region of the atmosphere ($\chi > 200 \text{ g cm}^{-2}$), the angular dependence of F in the atmosphere is known to be fairly well represented by

$$F(\theta, \text{surface}) - F(0, \text{surface}) \cos^n(\theta) \quad [9]$$

in terms of the vertical flux, $F(0, \text{surface})$ in the atmosphere, that is, the cosmic ray flux on the surface of the object. The value of n is 2.3 ± 0.3 (Conversi and Rothwell, 1954; Lal, 1988a). Equation [3] readily adapts itself to an object whose dimension is changing as a result of erosion (Lal and Chen, 2005).

The distribution of path length vectors within a target can easily be derived. This task has been carried out earlier in similar contexts (Bhattacharya et al., 1973; Lal, 1972; Lal and Chen, 2005). For calculations of nuclide production rates in large boulders, see Masarik et al. (2000), Masarik and Wieler (2003), and Lal and Chen (2005). The latter authors have also considered relative nuclide production rates within rectangular bodies. They have concluded that since cosmic ray interactions are highly dependent on the geometry of exposure of the target, an examination of nuclide concentrations within a large target can be used to constrain the exposure history of objects, as their surfaces evolve due to weathering and erosion. This is a unique feature of the TCN 'exposure age dating,' vis-É-vis other nuclear methods (Lal, 1991).

Conclusions

In the past five decades and beyond, a great deal has been learned about the composition and fluxes of cosmic ray particles on the Earth, as well as about their most significant origins in the galaxy. The primary cosmic ray beam is composed of the ordinary matter we see in the universe, mostly H nuclei, since this is most abundant in the cosmic matter. The incidence of the cosmic radiation on the Earth's atmosphere leads to a very complex cascade of nucleons, mesons, muons, and a variety of elementary particles and soft cascades composed of electrons and positrons. In this article, the discussion has been confined to the primary cosmic rays and their composition; the composition of the secondary particles and their inelastic nuclear interactions leading to changes in the nuclear composition of matter. Knowledge of the primary cosmic radiation and its temporal variation due to solar modulation, and the development of the secondary cosmic ray beam are essential for accurately deducing the production of new forms of matter in cosmic ray interactions in the atmosphere as well as in solids in the lithosphere.

One may wonder how it is possible to deal practically with the above problem in spite of its complexity. The text shows that a fair amount of success has been achieved in this attempt, and there is no doubt that further improvements will be made in the future.

Appendix A Units Used in Cosmic Ray Physics

Since we are dealing with nuclear size particles, and since we generally deal with relativistic particles (velocities comparable to the speed of light, c), we work with a special unit system

appropriate to particle masses and energies. The units and important relations between particle velocities, momentum, rigidity, and energy are defined below.

The unit of energy is electron volt, the kinetic energy gained by an electron when it is raised in potential by 1 V (the energy gained by an He nucleus in being raised by 1 V would be 2 eV). One electron volt equals 1.6×10^{-12} erg of energy (one electron charge = 4.8×10^{-10} e.s.u. (1.6×10^{-20} e.m.u.) and $1 \text{ V} = 1/300$ e.s.u. (10^8 e.m.u.)).

At relativistic energies, when particle velocities are comparable to speed of light, the following relations hold between momentum, p , and rigidity, R (m is the particle mass at rest, and c is the speed of light in vacuo):

$$E = mc^2\gamma \quad [A.1]$$

$$\gamma = \frac{1}{\sqrt{1 - (v/c)^2}} \quad [A.2]$$

$$p = mv\gamma; \quad pc = mc^2\left(\frac{v}{c}\right)\gamma \quad [A.3]$$

$$R = \frac{pc}{Ze} \quad [A.4]$$

E is defined as the total energy (rest mass + kinetic energy, E_k). When vc , $\gamma \approx 1$, the total energy is close to its rest mass: m_0c^2 . At Newtonian velocities, vc , the kinetic energy can be seen to be equal to $(1/2)mv^2$, from binomial expansion of eqn [A.1].

The particle rigidity is so defined (eqn [A.4]), based on the movement of a charged particle in magnetic field, balancing the centripetal force on the particle with the Lorentz force (Rossi and Olbert, 1970). The units of E , p , and R are electron volt (eV), eV/ c , and volt (V), respectively.

Energy and momentum are related to each other by a very useful relation, as can be seen by using eqns [A.1] and [A.3]:

$$E^2 = (E_k + mc^2)^2 = (pc)^2 + (mc^2)^2 \quad [A.5]$$

Appendix B Definitions of Cosmic Ray Flux, and Geometric and Absorption Nuclear Interaction Rates

Crossing and Omnidirectional Fluxes

Unidirectional flux, $j(\theta, \phi)$, of cosmic ray particles arriving from any specified direction is defined as the number of particles per unit time, per unit solid angle, striking 1 cm^2 of a plane surface-oriented perpendicular to the incident direction; see Figure 6 for definitions of θ (zenith angle) and ϕ (azimuthal angle) shown schematically around a sphere of radius, r . It then follows (since differential solid angle, $d\omega = \Delta A/r^2$) that the 'total' number of particles striking a horizontal area, 1 cm^2 per unit time, F is given by:

$$F(\text{cm}^{-2} \text{ s}^{-1}) = \int_{\theta} \int_{\phi} j(\theta, \phi) \cos(\theta) \sin(\theta) d\theta d\phi \quad [B.1]$$

The $\cos(\theta)$ term in eqn [A.1] arises from the definition of 'flux.' It is often convenient to define an 'omnidirectional flux,' F_{omni} , the total number of particles striking an unit sphere of projected area 1 cm^2 from all directions, based on the definition of the unidirectional flux, $j(\theta, \phi)$:

$$F_{\text{omni}}(\text{cm}^{-2} \text{s}^{-1}) = \int_{\theta} \int_{\phi} j(\theta, \phi) \sin(\theta) d\theta d\phi \quad [\text{B.2}]$$

The secondary cosmic ray fast nucleon flux in the atmosphere at depths $>200 \text{ g cm}^{-2}$ shows a steep dependence with θ ($\cos^{2.3}(\theta)$) since particles incident at greater zenith angle traverse greater amount of matter in the atmosphere (cf. [Conversi and Rothwell, 1954](#)).

Nuclear Interaction Rates

The rate of nuclear reactions resulting in the production of a nuclide of interest in 1 g target, q (nuclei/g target/s), by particles of kinetic energy, E , in the specified target atoms are given by the relation

$$q(\text{nuclei/g target/s}) = F_{\text{omni}} n \sigma_i(E_k) \quad [\text{B.3}]$$

$$= n \int_{\theta} \int_{\phi} \int_{E_k} j(\theta, \phi, E_k) \sigma_i(E_k) r \sin(\theta) r d\theta d\phi \quad [\text{B.4}]$$

where n is the number of specified atoms in 1 g of the target, and $\sigma_i(E)$ is the kinetic energy-dependent partial cross-section for the formation of a nuclide. Note that in eqn [B.4], the term $\cos(\theta)$ in the double integral of eqn [B.1] is missing since particles incident at zenith angle, θ , have a longer path length in the unit target volume by a factor of $\sec(\theta)$. Here lies the utility of the concept of omnidirectional flux, F_{omni} .

Geometric Nuclear Interaction and Nuclear Absorption Cross-Sections

For fast nucleons (neutrons or protons), the total geometric nuclear interaction cross-section, σ_g , of a nucleus of mass number A is given by the following relation:

$$\sigma_g = \pi r^2 = \pi r_0^2 A^{2/3} \quad [\text{B.5}]$$

where r is the effective nuclear radius and r_0 is the nucleon radius, taken to be $1.20 \times 10^{-13} \text{ cm}$ ([Lang, 1980](#)). Equation [B.5] assumes constant density of nuclear matter in complex nuclei. The geometric mean free path for nuclear interaction, λ , is defined as (see eqn [A.3])

$$\lambda = \frac{1}{n\sigma_g} \quad [\text{B.6}]$$

The effective absorption cross-section for fast nucleons is smaller than the geometric nuclear interaction cross-section as the incident nucleon retains a large fraction of its initial kinetic energy (see text). If the elasticity, that is, the fraction of energy retained by the nucleon after interaction, is η , then it can be shown that for a power law nucleon differential spectrum of the form $a \times E_k^{-\Gamma}$ (the emerging nucleons retain the same spectral form, and are attenuated with an absorption mean free path, Λ :

$$\Lambda = \frac{\lambda}{1 - \eta^{\Gamma-1}} \quad [\text{B.6a}]$$

The corresponding effective absorption cross-section, σ_a is

$$\sigma_a = \sigma_g(1 - \eta^{\Gamma-1}) \quad [\text{B.7}]$$

The above equations are valid for treatment of propagating flux of secondary high-energy nucleons in the atmosphere produced from primary protons of $E_k \geq 3 \text{ GeV}$.

The calculated value of the geometric mean free path of nucleons in air is 90 g cm^{-2} . The corresponding values of the absorption mean free path of nucleons in air for $\eta = 0.50, 0.55$, and 0.60 are $155, 169$, and 187 g cm^{-2} , respectively. The value of Γ has been taken to be 2.5 in these calculations.

Appendix C Modulation of Cosmic Ray Flux by the Geomagnetic Field; Cutoff Rigidity and Kinetic Energy

Before entering the Earth's atmosphere, primary cosmic ray particles being charged are influenced by the Earth's magnetic field. The present geomagnetic field is well represented by a dipole of strength, $M = 8.1 \times 10^{25} \text{ G cm}^3$, located 342 km from the Earth's geometric center, with its axis intersecting the Earth's surface at 78.50° N , 69.00° W and 78.50° S , 111.00° E ([Sandström, 1965](#)). The geomagnetic field acts as a rigidity analyzer. For any hypothetical direction of arrival, one can define a particle momentum, p_u , such that particles of this momentum arriving from infinity can reach the given point from all directions. Similarly, one can also define a rigidity value, p_c , so that particles of lower momentum cannot arrive the given point in a given direction. For particle rigidities between p_u and p_c , there are 'forbidden' and 'allowed' bands of momenta. Reference is made to [Peters \(1958\)](#), [Sandström \(1965\)](#), and [Pomerantz \(1971\)](#) for further details.

If one neglects the fact that the magnetic dipole is shifted from the Earth's geometric center, and also the fact that the Earth is not a perfect sphere, the minimum cutoff momentum, p_c , which a particle must have is given by

$$p_c = \frac{M}{r_e^2} \frac{\cos^4(\lambda)}{[1 + \sqrt{1 - \sin(\theta) \cos(\phi) \cos^2(\lambda)}]^2} \quad [\text{C.1}]$$

$$= 59.6 \frac{\cos^4(\lambda)}{[1 + \sqrt{1 - \sin(\theta) \cos(\theta) \cos^2(\lambda)}]^2} \text{ GeV/c} \quad [\text{C.2}]$$

where r_e is the Earth's radius, θ and ϕ are respectively the zenith angle and azimuthal angles of the particle, and λ is the geomagnetic latitude. For vertical incidence, the corresponding cutoff rigidity, R_c (rigidity being defined as $R = p_c/Ze$; see [Appendix A](#)), is given by:

$$R_c = 14.9 \cos^4(\lambda) \text{ GV} \quad [\text{C.3}]$$

The corresponding vertical cutoff kinetic energy, E_c (kinetic), of the particle can be estimated using relation [A.5]. The minimum kinetic energy of a vertically incident proton at geomagnetic latitudes of $0^\circ, 10^\circ, 20^\circ, 30^\circ, 40^\circ, 50^\circ, 60^\circ, 70^\circ, 80^\circ$, and 90° are respectively $14.0, 13.1, 10.7, 7.49, 4.28, 1.77, 0.384, 0.02, 0.0001$, and 0 GeV .

The geomagnetic coordinates in the centered dipole approximation can be estimated from the corresponding geographical coordinates (cf. [Hopper, 1964](#); [Sandström, 1965](#)).

Introduction

Cosmogenic nuclides are produced *in situ* within minerals exposed at the earth's surface as a result of interactions of cosmic rays with the nuclei of target elements. Because cosmogenic nuclides build up predictably with time, measuring their concentrations allows the determination of how long a rock surface or sediment has been at or near the surface of the earth (Gosse and Phillips, 2001). The radionuclides ^{10}Be , ^{14}C , ^{26}Al , and ^{36}Cl and the noble gases ^3He and ^{21}Ne are the most commonly used cosmogenic nuclides today. With cosmogenic nuclide methods, rock surfaces and sediment can be directly dated (Figure 1). This is a unique and powerful tool available only to geomorphologists for roughly the last 25 years. Bedrock landforms, such as fluvially or glacially polished bedrock surfaces, fault footwall faces, and landslide bedrock detachment surfaces, can be dated directly. Sedimentary units such as moraines, landslide debris, fluvial terraces, debris-flow deposits, or alluvial fans can be directly dated by sampling boulder surfaces or by taking samples made up of numerous clasts or by taking sand samples. Geochronological questions that were previously difficult to solve due to the limitation of finding organic material for radiocarbon dating or by the 50-ka upper limit of radiocarbon dating can now be addressed with cosmogenic nuclides. Similarly, depositional landforms whose ages far exceed the upper limit or whose sediment does not fulfill the requirements of luminescence techniques (complete bleaching of the quartz or feldspar grains) can be studied. But more can be learned from the concentrations of cosmogenic nuclides than just the age. The dates themselves are used as a tool to glean fundamental information about rates and styles of geomorphic processes. In this article, the ways in which cosmogenic nuclides are used to date various landforms are described. In addition, examples where the obtained ages are used to calculate the rates of geomorphic processes are highlighted. A number of review articles provide excellent overviews as well as comprehensive reference lists (Bierman and Nichols, 2004; Bierman et al., 2002; Cockburn and Summerfield, 2004; Gosse and Phillips, 2001; Ivy-Ochs and Schaller, 2010; Morris et al., 2002).

Although the focus here is on the dating of landforms, cosmogenic nuclides have a largely untapped potential in archaeology, for example, the dating of man-made structures and lithic artifacts (Akçar et al., 2008 and references therein) and use of burial dating of sediments to date early hominids (Partridge et al., 2003).

Dating Rocks and Sediment with Cosmogenic Nuclides

The cosmogenic nuclide methods available to date landforms may be broadly divided into two categories: buildup and decay methods. The former includes exposure dating of boulders or

clasts and depth-profile dating with clast or sand samples. Decay methods include burial and isochron dating. The appropriate cosmogenic nuclide method for dating a given landform is largely dependent on the character of the deposit, which in turn depends on the depositional processes and the age and state of preservation of the landform; where possible, several methods are combined.

If large boulders are present on the top surface of the landform, these are often the most suitable sample material. In order to use the exposure age of a boulder surface to date a landform, the rock surface must have undergone single-stage (no preexposure), continuous (not covered) exposure in the same position (not shifted) since deposition. Thus, limitations are imposed on the landforms that can be dated; they must have formed rapidly and be no longer active. Exposure dating is then used to establish the end of the period of activity. In older deposits, surface degradation and boulder spalling and crumbling often lead to smoothing out of the original surface. In these cases, individual or amalgamated clast samples from the surface or along depth profiles are analyzed. For even older deposits (more than several 100 ka), burial or isochron dating methods are called upon.

In dating, the possibility of inherited nuclide concentrations (preexposure) must be considered. Inheritance may have built up in the bedrock setting or in the storage of sediment prior to deposition on the landform of interest. The amount of inheritance acquired in the bedrock setting is related to how deep in the bedrock the boulder originated and how long that bedrock surface was exposed. The effect on the calculated age (how much 'too old') depends on what proportion of the final measured concentration can be attributed to inherited nuclides. The inherited component will be proportionately greater in rocks stemming from long-exposed bedrock surfaces that are finally deposited in very young (Holocene) landforms.

Rock surfaces are constantly undergoing weathering (erosion). As a rock surface weathers, the outermost layers with the highest concentrations of cosmogenic nuclides are removed. This lowers the concentration and, consequently, the calculated apparent exposure age. As an aside, we note that, because of the shape of depth profile of ^{36}Cl production, ^{36}Cl ages on eroding surfaces may sometimes be apparently 'older' (see Gosse and Phillips, 2001). For calculating exposure ages from a single nuclide concentration, either an erosion rate of zero or a reasonable erosion rate for that rock surface is assumed. Crystalline rock erosion rates are generally less than 5 mm ka^{-1} (Cockburn and Summerfield, 2004).

Radionuclide concentrations build up in exposed minerals until secular equilibrium (saturation) is reached. At secular equilibrium, the number of nuclides produced per unit time is equal to the number that decays; the concentration is at steady state. This is shown by the flattening out of the nuclide

Figure 1 Examples of exposure dated landforms and rock surfaces. (a) Boulder dated from the Kromer moraine (Austria; Kerschner et al., 2006); view is down valley; moraine ridge continues to the right. (b) Pahoehoe flow top from the ca. 90 000-year-old (^3He) Bar Ten flow, Arizona (Fenton et al., 2001). (c) Beryllium-10 dating of boulders indicates that this lobe of the Shephard Creek fan in Owens Valley (California) is Holocene in age (Dühnforth et al., 2007); view is up into the catchment. (d) Continuous sampling of the Kaparelli limestone fault surface (Greece) for ^{36}Cl exposure dating (Benedetti et al., 2003).

concentration growth versus time curve after 3–4 half-lives (Figure 2). Both erosion and decay lead to loss of nuclides, and saturation is reached earlier (after a shorter exposure period; lower lines on Figure 2 for several different erosion rates).

In principle, when the concentrations of two nuclides from the same rock surface are measured, exposure time, erosion rate, and the presence of past coverage (complex exposure) may be revealed. An elegant way of portraying two-nuclide data is the erosion-island plot (Figure 3(a) and 3(b); Lal, 1991). Data for two nuclides with relatively long half-lives are well suited to study landforms in settings characterized by very low erosion rates and, thus, old rock surfaces (e.g., as in arid regions; see below). The erosion-island plot is especially useful for quick and clear identification of data points that represent continuous, single-stage exposure (plot in or near the erosion island) versus those that reflect complex exposure by burial. As a result of the difference in the half-lives of two nuclides (e.g., ^{26}Al and ^{10}Be), the length of time that sediments have been buried can be determined. When sediment is completely shielded, the changes in concentrations are dependent only on the half-lives. Aluminum decays faster, so the ratio $^{26}\text{Al}/^{10}\text{Be}$

decreases with time and the data points plot below the erosion island in the Al–Be erosion-island plot (Figure 3(c)) and above in the Be–C and Ne–Be plots (Figure 3(a) and 3(b)). It is important to note that there is no location on the diagram that can be reached by only one pathway. Data points for rock surfaces or sediment that were exposed and then buried can arrive back inside the erosion island after a long enough period of (re-)exposure. For points below the erosion island in the Al–Be plot, the minimum time to reach that point is made up of continuous exposure along the outer line followed by burial with complete shielding (zero production). All other possible scenarios (partial shielding or repeated burial and exposure) require more time (cf. Bierman et al., 1999). As seen in Figure 3(b), the use of ^{21}Ne (stable) along with ^{10}Be provides increased sensitivity for older, more slowly eroding surfaces. The recent addition of ^{14}C (Figure 3(a)) to the nuclide palette (Lifton et al., 2001) allows periods of burial during the last 10–15 thousand years to be identified (Goehring et al., 2011; Miller et al., 2006). Such recent intervals of burial cannot be accessed with the longer lived (or stable) nuclides.

Figure 2 Increase in ^{10}Be and ^{21}Ne concentrations with time. With erosion, saturation is reached earlier and at lower concentrations. ^{10}Be production as in Balco et al. (2008), ^{21}Ne production rate after Kober et al. (2011), both at sea level and high latitude (SLHL). In the case of saturation, a minimum age or a maximum erosion rate can be derived.

Figure 3 Erosion-island plots: $^{10}\text{Be}/^{14}\text{C}$ versus ^{10}Be (a); $^{21}\text{Ne}/^{10}\text{Be}$ versus ^{10}Be (b); $^{26}\text{Al}/^{10}\text{Be}$ versus ^{10}Be (c); all at sea level and high latitude (SLHL). With time, nuclide concentrations increase and, as the several nuclides decay with different rates, the nuclide ratio decreases (Al/Be) or increases (Ne/Be and Be/C) with time. For a continuously exposed rock surface with no erosion and no coverage, a data point would follow on the 'zero erosion' trajectory (sample point A). Periods of exposure are shown as black points on the outer black line. The blue lines inside the erosion island are trajectories for rocks continuously exposed and undergoing continuous erosion (sample point B). A data point on the erosion saturation line (inner black line) indicates secular equilibrium of both nuclides with respect to a specific erosion rate (sample point C). The field between the zero erosion line and the erosion saturation line is referred to as the erosion island. Data points may plot in the field below (Al/Be) or above (Ne/Be and Be/C) the erosion island if the rock surface has been buried (e.g., by ice or sediment) and/or if thick slabs (tens of centimeters) have spalled off (Bierman et al., 1999; Kober et al., 2007). Green lines show data point trajectories after burial. Note the very different temporal ranges that are accessible when ^{14}C is included. The combination $^{14}\text{C}/^{10}\text{Be}$ has its strongest advantage in complex exposure history studies covering the last 10 000 years.

The Spectrum of Dated Landforms

Glacial and Periglacial Landscapes

Glaciers respond rapidly to changes in temperature and precipitation and therefore are very sensitive indicators of climate change. A striking example is the nearly synchronous behavior of glaciers worldwide during the Little Ice Age. Prior to exposure dating, the timing of glacier size variations was approximated on the basis of correlation with local radiocarbon-dated records or with regional or hemispheric records, such as ice cores or marine sediment cores. But this fitting into an established chronology meant that the information on past climate change contained in the glacial record itself was lost. The direct dating of boulders on moraines with cosmogenic nuclides is one of the most powerful tools for reconstructing the timing of past glacier volume changes (Gosse, 2005).

The time of stabilization of a moraine is determined by measuring the concentration of cosmogenic nuclides in the surface of the largest boulders on the crest of the moraine (Figure 1(a)). Ideally, the signal recorded is the point of abandonment of the moraine by the glacier. Moraines ranging in age from hundreds of years (Schaefer et al., 2009) to hundreds of thousands of years have been dated. Limiting factors are the weathering of the boulder surface and the degradation of the moraine itself. Degradation of moraines as well as the associated exhumation and instability of boulders poses a severe limitation to accurate moraine dating (Putkonen and Swanson, 2003). In contrast, preexposure in moraine boulders is uncommon (Heyman et al., 2011; Putkonen and Swanson, 2003) but has been encountered (Briner et al., 2005). Reflecting the long-term instability of the landform, on older moraines that contain fewer boulders the spread in ages is greater (Kaplan et al., 2005). In dry climate regimes, for example in Patagonia, clasts on outwash deposits have been dated (Hein et al., 2009). The success of this approach highlights the inherent stability of the flat outwash deposit versus the instability of moraines. Similarly, as degradation leads to a change in the shape of a moraine with time, depth-profile dating in the till has proven difficult. Schaller et al. (2009) determined ages tens of thousands of years younger with depth profiling than ages determined originally by exposure dating of boulders on the moraine crest (Gosse, 2005).

Dating of glacially modified bedrock surfaces, such as roches moutonnées, may provide information about the timing of initial deglaciation of the valley bottom, from which retreat rates of glaciers are calculated (Guido et al., 2007). However, results from bedrock surfaces should be viewed with caution. Often, where excellent glacial polish is observed, the rock surface has been covered and protected, making it unsuitable for exposure dating (determined ages are less than the true age of formation). Reflecting the spatial variability of subglacial erosion, bedrock surfaces may contain inherited nuclides where less than about 2 m of rock was removed. Fabel et al. (2004) used this fact to estimate glacial erosion rates of bedrock at the bottom and along the sides of U-shaped valleys in the Sierra Nevada and Wind River Ranges. The presence of inheritance in glacially modified bedrock prompted Dühnforth et al. (2010) to highlight the importance of lithological control on glacial erosion. Two-nuclide data, for example, $^{26}\text{Al}/^{10}\text{Be}$ ratios, plot below the erosion island when

exposure was not continuous and the bedrock was (repeatedly) covered but not eroded by the ice (Bierman et al., 1999; Staiger et al., 2005). With *in situ* ^{14}C , periods of ice cover in the Holocene are determined (Goehring et al., 2011; Miller et al., 2006).

Cosmogenic nuclides are used to date the end of periods of activity and thus to pinpoint the melting out of permafrost from periglacial landforms, such as rock glaciers (Ivy-Ochs et al., 2009a) and block streams (Barrows et al., 2004). This affords the previously unrealized opportunity to decipher the climate signal contained in periglacial landforms. Periods of enhanced talus production are also determined with cosmogenic nuclides (Ballantyne and Stone, 2009).

Volcanic Terrains

Cosmogenic nuclides can be used to provide information about eruptive sequences of lava and ignimbrite flows. In addition, the dating of volcanic landforms allows the determination of fluvial incision rates and, when they are offset along a fault, slip rates. Exposure dating in mafic volcanic terrains has been carried out with the cosmogenic noble gases ^3He and/or ^{21}Ne (Cerling and Craig, 1994), because they are more suitable for analysis in mafic phenocrysts (olivine and pyroxene). Chlorine-36 is suitable for whole rock determinations on volcanic rocks, thus allowing dating of aphyric lavas (Phillips, 2003). To determine the eruptive age of the lava flow and develop a chronology for the flows in a volcanic field, original eruptive surfaces must be clearly identified; primary eruptive features, such as spatter and frothy glassy texture of the cooling rinds, are sought (Blard et al., 2005; Cerling and Craig, 1994; Fenton et al., 2001; Phillips, 2003; Figure 1(b)).

Alluvial Fans

Surface exposure dating is used to date the time of abandonment of alluvial fan lobe surfaces. Lobe abandonment is the result of fans moving laterally along a fault away from the locus of deposition, or of avulsion or fan head incision events. Alluvial fans build up through a variety of processes, including fluvial flow, overland flow, debris flow, rock avalanche, and rockfall. The architecture of alluvial fan sediments often records changes in the catchment driven by either climate or tectonics. The cosmogenic nuclide method appropriate for dating a given fan depends on the depositional processes and the age of the fan. Fan surfaces are dated to determine slip rates along faults (Meriaux et al., 2005; Siame et al., 1997) or in studies aimed at elucidating temporal variation of catchment processes (Dühnforth et al., 2007). Dates from fan abandonment times based on cosmogenic nuclides are compared with luminescence dates, which give the time elapsed since burial of the dated sediment (Guralnik et al., 2011). Much older fans are dated with cosmogenic nuclides (Nishiizumi et al., 2005) rather than with radiocarbon or luminescence dating.

Effective dating of fans requires that they are built up over a relatively short time interval, on the order of thousands of years (Hancock and Anderson, 2002). On younger surfaces, the largest boulders are dated (Figure 1(c); Dühnforth et al., 2007). On older alluvial fans (more than one or two hundred thousand years), degradation of fan surfaces and boulder

Figure 4 Depth profiles of ^{21}Ne reflecting various geomorphic processes. Depth profiles for alluvial landforms: erosion rate of top surface is zero. (a) Depth profile showing nuclide buildup with time. (b) A flat profile in the upper few tens of centimeters may indicate soil or regolith production, bioturbation, cryoturbation, or creep processes (Phillips et al., 1998). (c) The presence of inherited nuclide concentrations in the sampled sediment is indicated by the offset to higher concentrations at several meters depth (compare with (a)). (d) Two periods of aggradation; the blue line shows continuous exposure of the first unit (the lower section) followed by aggradation on top of it at a rate of centimeter per thousand years. The pink line portrays two separate single aggradation cycles each leaving 1 m of sediment.

weathering lead to smoothing out of the fan surface (Matmon et al., 2005). Such fans are dated with samples comprising individual clasts, tens of clasts, or sand samples from the surface or in depth profiles (Guralnik et al., 2010; Meriaux et al., 2005). For even older deposits (more than several 100 ka), burial or isochron dating methods are called upon. Samples are collected from the highest and flattest part of the surface away from diffusing slopes. Inheritance is a serious concern in the dating of alluvial fans. It could have been acquired during hillslope weathering in the catchment especially where if denudation rates are low. Also, clasts may have been exposed during intermittent storage in terraces in the catchment before final deposition on the fan. Cosmogenic nuclide results also show that many clasts do not come from the catchment during the event from which they are deposited. They may be scavenged from higher elevation fan lobes upstream (Ward et al., 2005).

Two considerations are crucial: (i) the amount of inheritance in the clasts and (ii) the degradation or aggradation rate of the top surface. These issues are addressed by measuring depth profiles that extend to several meters (Anderson et al., 1996; Braucher et al., 2009; Hidy et al., 2010). The shape of the concentration versus depth curve depends on the exposure age, the erosion (or aggradation) rate, and the amount of inheritance (Figure 4(c) and 4(d)). Where field relationships indicate that the top of the depositional surface has undergone little erosion (flat tread morphology as opposed to convex terrace

tops) or little aggradation (minimal silt layer below the top surface pavement), the shape of the depth curve reveals both age and inheritance (Figure 4(a)). Often, mixing of the upper 40–50 cm of sediment leads to the lack of a decrease in nuclide concentrations in the upper several tens of centimeters (Figure 4(b); Phillips et al., 1998). Depth-profile results that indicate separate depositional units (Figure 4(d)) are evaluated in the light of field evidence.

The dating of fluvial landforms is used to determine incision rates. The height and age of abandoned bedrock strath terraces (Burbank et al., 1996) or fluvial cut-fill (Ward et al., 2005) located along a given reach of a river provide information about fluvial incision rates and their variation with time. Sampled bedrock surfaces bear scars of fluvial erosion, provided they have not been covered for any extended period by sediment. Boulders or amalgamated clast samples on debris-flow deposits on ancient straths are dated to determine fluvial incision rates (Fenton et al., 2004). Fluvially sculpted channel walls may provide a more continuous record of incision than strath terraces (Schaller et al., 2005).

Rates of Tectonic Activity

Cosmogenic nuclides are used to determine rates of tectonic activity by means of two approaches: (i) by indirectly measuring the slip rates along faults or growing folds by determining

the ages of deformed or offset abandoned landforms; and (ii) by direct dating of bedrock fault surfaces produced during rupture events. Determined rates can be compared along various segments of a fault as well as through time.

Slip rates on strike-slip faults or rates of uplift on normal faults are determined by taking the amount of offset of the dated feature and its age. Offset alluvial fans (see above), fluvial terraces, river channels, diffused hillslopes, moraines, and lava flows have been dated for slip-rate determinations (Fenton et al., 2001; Meriaux et al., 2005).

With cosmogenic nuclides, the limestone bedrock surfaces created during normal faulting are dated directly with ^{36}Cl . Continuous sampling is done along an exposed bedrock fault face (Figure 4(d)). Nuclide concentrations are plotted versus height above the base of the scarp whereby a pattern of steps in concentration is revealed. The steps are interpreted to represent periods of exposure separated by earthquake-related rupture events (Benedetti et al., 2003; Mitchell et al., 2001; Zreda and Noller, 1998). Recent improvements to the calculations allow statistical evaluation of the concentration jumps (Schlenger et al., 2011).

Landslide Dating

Landsliding is a key process for the adjustment of steep (often glacially oversteepened) slopes, for modification of valley cross profiles, as well as for overall landscape denudation in mountainous terrain. By determining the timing of recurrence intervals, especially for high-magnitude events, we can begin to understand the mechanisms of large-scale downslope movement of rock, as well as the interplay between the various possible causes and triggers. New rock surfaces suitable for exposure dating are created during large deep-seated gravitational movements. Each possible sampling site (head scarps, sliding planes, large boulders in the deposit) has its own advantages and disadvantages with respect to exposure dating (Ivy-Ochs et al., 2009b). In the detachment scarp, post-slide rock fall can be difficult to identify. Shallow sliding planes may yield too young ages as a result of coverage by snow and/or vegetation, although when sliding planes dip steeply, consistent results may be obtained. Data from a number of sites where landslide boulders contain inheritance provide direct confirmation of modeling, which shows that large boulders are carried along on the surface during movement. Preexposure in moraine boulders is rare (Heyman et al., 2011), while in landslide boulders it is common (Ivy-Ochs et al., 2009b), especially in regions that were not glaciated, thus with higher nuclide concentrations in the pre-slide bedrock. Recent results dating historic landslides (Akcar et al., 2012) underline the importance of landslide dating for determining nuclide production rates.

Dating of Paleoshorelines

Ancient shorelines may be marked by wave-cut bedrock platforms or by scattered loose clasts aligned along ancient strandlines. To access the climate signal contained in the record of higher sea level or high lake stands in arid regions, a time frame

is required. When the time of formation is known, the height of uplifted bedrock platforms can be used to estimate coastal rock uplift rates (Alvarez-Marrón et al., 2007). Exposure dating of bedrock platforms can be confounded by the presence of inherited nuclides. This may mean that not enough rock was eroded by wave action to re-zero the bedrock (a minimum of several meters depending on nuclide), or that the platform was reoccupied during successive high sea levels, or both. At Lake Lisan, problems with inheritance, pointing to intermediate storage of clasts, were encountered in dating the paleostrandlines (Matmon et al., 2003).

Arid Regions

Cosmogenic nuclide methods are well suited to the dating of rock surfaces in the arid and hyperarid deserts of southern Africa (Fleming et al., 1999), south-central Australia (Belton et al., 2004), western South America (Kober et al., 2007; Nishiizumi et al., 2005), and Antarctica (Sugden et al., 2005). High concentrations of long-lived radionuclides (^{10}Be , ^{26}Al) and stable nuclides (^3He , ^{21}Ne) measured on bedrock or low-relief alluvial surfaces confirm the antiquity of these landscapes. Multistage exposure (with intervals of burial) and erosion rate histories can be deciphered by measuring different cosmogenic nuclides with different half-lives from individual surfaces (Kober et al., 2007). At several sites, data points plot within the erosion island, pointing to single-stage exposure history, but do not plot on the erosion saturation line (Figure 3) as would be expected for continuous exposure for millions of years. It is important to recognize that both burial and slab breakoff can lead to such nuclide ratios (Bierman et al., 1999; Kober et al., 2007). Maximum erosion rates for the rock surfaces are calculated by assuming that nuclide concentrations are in steady state. At several of these sites, erosion rates of 1 mm ka^{-1} or even less have been determined (Cockburn and Summerfield, 2004).

Cosmogenic nuclides have also been used to study sand dunes (Nishiizumi et al., 1993; Vermeesch et al., 2010). By analyzing ^{10}Be , ^{26}Al , and ^{21}Ne in sand grains, Vermeesch et al. (2010) found that the Namibia sand sea prevailed despite major variations in climate during the Quaternary.

Summary and Outlook

The ability to use cosmogenic nuclides to determine how long rock surfaces have been exposed at the surface of Earth provides an unrivaled tool for determining the ages of landforms and therefore the rates of geomorphic processes. Rocks on landforms that have been exposed for hundreds of years (landslides and moraines), hundreds of thousands of years (alluvial fans and river terraces), or to millions of years (ancient bedrock landforms) can be dated with cosmogenic nuclides. Only younger landforms (less than several hundred thousand years) are dated with exposure dating of boulders. For older landforms, surface amalgamated clast samples, sand clasts in depth profiles, or burial dating is required. This broad spectrum of available dating methods allows the dating of numerous depositional landforms as well as many bedrock

landforms. As knowledge of production rate and scaling formalities improves, there is improvement in the precision of obtained ages. But the accuracy of the ages remains a question of geological uncertainties. Both rock surfaces and landforms degrade with time. This imposes clear limitations on the useful time range as well as the accuracy of dating. Similarly, the natural variability of samples depends on landform morphology and age. Consequently, the obtained exposure ages must be evaluated individually. The ages must conform to field relationships such as terrace or moraine stratigraphy and regional morphostratigraphic relationships, as well as independent age constraints for the same or correlative features.

Glossary

Cosmogenic nuclide: A type of atom produced by a nuclear reaction with a secondary cosmic ray.

Muon: A type of secondary cosmic ray particle.

Nucleon: A neutron or a proton; a type of secondary cosmic ray particle.

Radioactive mean life: The time taken for a radioactive material to decay to $1/e$ of its abundance.

Saprolite: Weathered bedrock that retains some original structure.

Spallation: A type of nuclear reaction in which nucleons are lost from a nucleus in a collision.

Introduction

Landscapes evolve over time as material is eroded from bedrock, transported down hillslopes and river systems, and deposited in valleys or basins. River incision and aggradation transmit base-level change through a watershed and help determine how landscapes respond to external factors such as tectonic uplift or climate change. To understand how landscapes change over time, it is important to characterize both erosion rates and valley lowering rates. It is also important to establish the timing of major events in the landscape's history to understand its dynamic response to changes in tectonics, climate, or other factors. Cosmogenic nuclides have played a key role in quantifying both erosion rates and the timing of landscape evolution.

Until recently, the task of measuring erosion rates had been very difficult. This was because eroding landscapes leave little sedimentary evidence of their past. Erosion rates, after all, are a measure of how fast material has been removed from a landscape. Most of the eroded material is either transported away or dissolved. It is possible to estimate short-term erosion rates from sediment and solute loads in streams, but sediment loads are susceptible to rapid fluctuations and their measurements are often fraught with error. Moreover, modern sediment loads are strongly influenced by land use. Prior to cosmogenic nuclide methods, the issue of land use was so daunting that it was considered questionable that erosion rates could ever be measured reliably in large parts of the world.

Today, the application of cosmogenic nuclide methods allows us to circumvent the problems of land use and to measure erosion rates over timescales of thousands of years. This is because the cosmogenic nuclides present in rock or soil today were produced by secondary cosmic rays passing through the rock or sediment above them in the past. Cosmogenic nuclide concentrations allow us to infer the presence of an overburden that is no longer there and how quickly it disappeared. Moreover, because cosmogenic nuclides persist in mineral grains for millions of years, they allow us to determine paleo-erosion rates in the distant past and to date important events in landscape evolution.

Cosmogenic Nuclide Buildup and Decay

Cosmogenic nuclides are such valuable monitors of surface processes because their production is rapidly attenuated within about a meter of the ground surface (Lal, 1991). Their buildup

in a mineral grain thus indicates how much time that grain has spent within the production zone. Many different cosmogenic nuclides are produced in different mineral grains, depending on the mineral composition. Cosmogenic nuclides used in landscape evolution include stable nuclides such as ^3He and ^{21}Ne , as well as radioactive nuclides such as ^{10}Be , ^{14}C , ^{26}Al , and ^{36}Cl (Cerling and Craig, 1994; Gosse and Phillips, 2001; Muzikar et al., 2003; Nishiizumi et al., 1993). Each of these nuclides can be used in a slightly different way, taking advantage of their production rates and decay times. The great majority of landscape evolution studies use the nuclides ^{10}Be and ^{26}Al in quartz. This is because production rates of these nuclides have a simple depth dependence, and because quartz is a common mineral grain that is resistant to chemical and physical weathering, allowing it to persist over long periods of erosion and transport (Lal and Arnold, 1985).

Aluminum-26 and ^{10}Be are produced by two different types of secondary cosmic ray particles that result from a nuclear cascade through the atmosphere (Lal and Peters, 1967). The first type of particle is a fast nucleon (these are mainly neutrons but include some protons) that causes a nuclear spallation reaction within mineral grains. For example, in quartz (SiO_2), a nuclear collision can cause ^{28}Si to undergo spallation to the lighter nuclide ^{26}Al through the net loss of a proton and a neutron. Likewise, ^{16}O can be transformed to ^{10}Be through the net loss of three protons and three neutrons. Spallation reactions such as these occur very near the ground surface, because fast nucleons are rapidly attenuated as they pass through matter. The penetration length of a fast nucleon depends on the density of the material that it is passing through, and is approximately 160 g cm^{-2} . For example, in typical rock of density 2.6 g cm^{-3} , the nucleons travel 60 cm; in typical soil of density 1.5 g cm^{-3} , the nucleons travel over a meter.

The second type of particle that produces ^{26}Al and ^{10}Be is a muon. Muons are less reactive than nucleons, so they produce fewer cosmogenic nuclides at the ground surface, only 2–3% of total production (Brown et al., 1995a); however, muons penetrate more deeply and dominate production at depths greater than a few meters. Although muons do not contribute much near the ground surface, they can account for up to 20% of the total cosmogenic nuclide inventory in an eroding terrain (Granger et al., 2001). Muons are very important for dating sedimentary deposits and for determining paleo-erosion rates because they continue to produce ^{10}Be and ^{26}Al even when sediment is buried at depth. A proper interpretation of

cosmogenic nuclide concentrations in a sedimentary deposit must account not only for the concentration inherited from the time of deposition, but also for postdepositional production by muons.

Determining Erosion Rates

To a close approximation, the depth dependence of ^{26}Al and ^{10}Be production can be described by the equation

$$P(z) = P_{\text{spallation}}(0)e^{-\rho z/\Lambda} + P_{\text{muon}}(0)e^{-\rho z/L} \quad [1]$$

where P is the production rate at depth z , the subscripts spallation and muon indicate production by the two separate mechanisms, ρ is the density, and Λ ($=160 \text{ g cm}^{-2}$) and L ($\sim 1300 \text{ g cm}^{-2}$) are the penetration lengths of fast nucleons and muons, respectively (Brown et al., 1995a; Lal, 1991). Although the depth dependence of muons varies from this simple approximation at depths greater than about 5 m (e.g., Heisinger et al., 2002), this equation will suffice for the purposes of discussion.

In an eroding landscape, mineral grains are exposed to an increasingly intense secondary cosmic ray flux as they are gradually exhumed from bedrock. In a slowly eroding landscape, mineral grains spend a lot of time near the surface and build up a large cosmogenic nuclide inventory; in contrast, in a rapidly eroding landscape, the mineral grains approach the surface quickly and are eroded away with only a small cosmogenic nuclide inventory. More quantitatively, the cosmogenic nuclide concentration at a rock surface can be found by integrating eqn [1] over time (Lal, 1991). For the case of long-term steady-state erosion, the concentration of a cosmogenic nuclide is given by eqn [2]

$$N = \frac{P_{\text{spallation}}}{(1/\tau) + (\rho E/\Lambda)} + \frac{P_{\text{muon}}}{(1/\tau) + (\rho E/L)} \quad [2]$$

where N is the concentration, E is the erosion rate, and τ is the radioactive mean life (a mean life is equal to a half-life divided by the natural logarithm of 2). The mean lives of ^{26}Al and ^{10}Be are approximately 1.0 and 2.0 million years, respectively.

It is important to realize that the timescale over which cosmogenic nuclides measure erosion rates is approximately the time taken to erode one fast nucleon penetration length (about 60 cm in rock; Lal, 1991). In most soil-mantled landscapes, erosion rates are averaged over a time that is comparable to that of soil formation. Cosmogenically derived erosion rates are usually averaged over a much longer timescale than that of agricultural land use and so primarily reflect a preagriculture rate (Brown et al., 1995b). The exception to this rule comes in rapidly eroding areas with a long history of land use, where several penetration lengths may have eroded away since the beginning of agriculture thousands of years ago. Cosmogenic nuclides not only circumvent the problem of land use in determining erosion rates, but also provide a useful tool for determining natural erosion rates as a baseline against which to ascertain the impacts of land use.

There are two different approaches to measuring erosion rates with cosmogenic nuclides. The first is to measure the erosion rate of a discrete site by analyzing material from the

surface of eroding bedrock or sediment. This can be either an eroding outcrop or a material from bedrock covered by soil (Figure 1). The latter case has been very important for understanding how erosion rates depend on soil cover.

The second approach is to measure erosion rates by analyzing sediment carried by streams. Streams sample eroded material from the entire watershed, providing a natural averaging mechanism (Figure 2). It can be shown that the average cosmogenic nuclide concentration in stream sediment reflects the average residence time of quartz in the watershed, even in a watershed eroding at different rates in different places (Granger et al., 1996). This is because of a self-compensating tendency in sediment mixing. Areas that erode quickly produce a lot of sediment, but with a low cosmogenic nuclide concentration. Areas that erode slowly do not contribute much sediment, but that which they do produce contains a high cosmogenic nuclide concentration. These two effects balance so that the average cosmogenic nuclide concentration indicates the average erosion rate of the watershed, over the time interval required to erode about one penetration length, or 60 cm. There are many complications that can lead to errors. Care must be taken to ensure that the source of quartz in the watershed is known, and that stream sediment is indeed derived from the whole watershed, not just from a local landslide, for example. Nonetheless, repeated studies have shown that basin-averaged

Figure 1 Cosmogenic nuclide concentrations in both bedrock (dashed line) and well-mixed soil (solid line) reach a value at the ground surface determined by the erosion rate (eqn [2]). Erosion rates can be inferred from cosmogenic nuclide concentrations in samples collected at the surface of eroding rock or soil, as well as from saprolite collected beneath a soil cover, as long as soil depth is known.

Figure 2 Cosmogenic nuclide concentrations in well-mixed stream sediment are determined by averaging a small amount of sediment from slowly eroding areas with a large amount of sediment from rapidly eroding areas. Neglecting radioactive decay, the average cosmogenic nuclide concentration is approximately given by eqn [2].

erosion rates can be accurately determined by this method (for a review, see [von Blanckenburg, 2005](#)).

Following are examples of each of these methods. The first example shows that bedrock erosion is highly dependent on the depth of soil cover. The second example shows that basin-averaged erosion rates are much more dependent on the long-term tectonic regime than on climate.

Example 1: Erosion Rates Beneath a Soil Cover – The Soil Production Function

It has long been postulated that the rate at which bedrock converted to soil depends on soil depth. Erosional processes such as animal burrowing and tree throw are more vigorous under a thin soil cover, but decline for thick soils. Likewise, freeze–thaw and wet–dry cycles are more effective under a thin soil cover. The functional form by which soil production depends on soil depth, however, has remained a matter of debate. Cosmogenic nuclides provide a way to determine this relationship directly, by measuring erosion rates in a single landscape.

[Heimsath et al. \(1997, 2010 and references therein\)](#) measured ^{10}Be concentrations in weathered bedrock beneath soil to determine the depth dependence of soil production rates. A successful experiment for determining the soil production function requires a landscape where both soil depths and erosion rates are likely to vary considerably. The landscapes they examined had thin soil on hill crests and ridges, and thicker soil in valley bottoms and hollows. All of their measurements were made on divergent hillslopes where it is most likely that soil is neither accumulating nor evacuating over time. The rate of soil production recorded by cosmogenic nuclides in this case is not the rate of chemical weathering, but is instead the rate of mechanical disruption of preweathered bedrock into mobile regolith. For a steady-state soil depth, this is equivalent to the denudation rate.

[Heimsath et al.](#) found that soil production rates decrease exponentially with soil depth, reaching a maximum under very shallow soils. This implies that soil production and erosion is stabilized by a negative feedback, so that soil depths tend to vary smoothly across a landscape and regulate erosion rates. If soils become thin in a particular place, then bedrock is decomposed more quickly to produce a thicker soil. Likewise, thick soils inhibit erosion so that soils eventually thin.

The fact that [Heimsath et al.](#) found thin soils and fast erosion rates on hill crests and ridges indicates that the landscapes where they worked are not in steady state, and that their relief is decreasing through time as the hill crests lower faster than the surrounding hillslopes, at least locally. This is not necessarily the case in all landscapes, however. In areas with more uniform soil depths or with large areas of exposed bedrock, the relationship between erosion rates and soil depth is less apparent ([Wilkinson et al., 2005](#)). Also, it should be realized that the rate of bedrock weathering to produce saprolite may have a different soil depth dependence than the mechanical disruption of saprolite into soil. Indeed, exposed bedrock erodes far more slowly than soil-mantled saprolite in many terrains ([Bierman, 1994; Granger et al., 2001; Heimsath et al., 2000](#)). A transition from soil mantled to bedrock topography is

one way that climate can affect erosion rates in arid environments ([Heimsath et al., 2010](#)).

Example 2: The Influence of Climate and Tectonics on Weathering and Erosion

Landscape-scale weathering and erosion rates depend on a wide variety of factors, including climatic parameters such as rainfall and temperature which have fluctuated dramatically through the Quaternary, as well as tectonic uplift rates, which vary at considerably slower rates. The issue of whether climate is more important than tectonics in determining regional erosion rates has been difficult to resolve using traditional methods. Many models have suggested that erosion rates may vary by orders of magnitude, for example, as rainfall increases from semiarid to humid environments. A suite of cosmogenic nuclide studies, however, has shown that although climate largely controls the degree of chemical alteration of rock as it is eroded, the net export of material from a watershed is closely matched to the long-term exhumation rate dictated by tectonics (see reviews by [Granger and Riebe, 2007; von Blanckenburg, 2005](#)).

The influence of climate

In a wide-ranging set of experiments, [Riebe et al.](#) analyzed ^{10}Be in sediment from nonglaciated granitic watersheds throughout a range of temperature and precipitation regimes to determine erosion rates (summarized by [Granger and Riebe, 2007; Riebe et al., 2003, 2004a](#)). They also inferred the degree of chemical weathering from the depletion of various elements relative to immobile zirconium.

[Riebe et al. \(2004a\)](#) found that although erosion rates were highly variable within a given climate regime, there is remarkably little variation in erosion rates between climate regimes. In other words, erosion rates show little dependence on climate. For example, in granitic sites throughout North America, extending over a mean annual temperature range from 2 to 25 °C and an annual precipitation gradient from 22 to 420 cm year⁻¹, they found no apparent pattern in erosion rates.

Although erosion rates do not depend on climate, the degree of chemical weathering does. For example, measurements at various altitudes in the Santa Rosa Mountains, Nevada, show that as vegetation decreases and snow cover increases, the degree of chemical depletion decreases from 20% to 0%, while the total erosion rate determined from ^{10}Be remains unchanged ([Riebe et al., 2004b](#)).

One implication of these studies is that the export of solutes from a watershed is generally limited by the supply of fresh minerals through physical erosion. A quickly eroding watershed in an arid environment supplies more solutes to the ocean than a slowly eroding watershed in a tropical environment ([Riebe et al., 2004a](#)).

The influence of tectonics

If erosion rates show such little dependence on climate, then what controls long-term erosion rates? A host of studies from throughout the world indicate that the long-term uplift and exhumation rate due to tectonics is the primary

control of short-term erosion rates (Riebe et al., 2001; von Blanckenburg, 2005).

One example where erosion rates have been quantitatively compared to known uplift rates is in Italy (Cyr and Granger, 2008; Cyr et al., 2010). Uplift rates have been quantified from well-dated marine terraces that ring the Italian peninsula and islands, and range from 0.2 mm year^{-1} in the north to 1.6 mm year^{-1} near the Straits of Messina in the south. Cyr et al. (2010) collected quartz sediment from streams draining landscapes with a variety of uplift rates. Although there was considerable scatter in the data reflecting stochastic erosional processes, the average erosion rate and the average uplift rate agree remarkably well in any given area. Deviations from this pattern occur where stream profiles showed strong convexities, indicating a landscape still undergoing a transient response to uplift.

Measuring River Incision and Valley Lowering Rates

River incision is intimately linked to basin-scale erosion. Rivers are the primary means for transporting sediment and solute from an eroding terrain. Rivers set the base level to which a watershed can erode. Because rivers can incise more quickly than hillslopes erode, they transmit base-level lowering signals to the basin's headwaters, thus regulating hillslope erosion in response to tectonic uplift and subsidence. Rivers also aggrade when they are choked by excess sediment from rapid hillslope erosion; thus alluvial sediments often provide a record of fluctuations in erosion rates. Cosmogenic nuclides can be used to study the history of river incision and aggradation by dating alluvial sediments, dating terraces, and dating caves alongside the river.

Over timescales of tens to hundreds of thousands of years, cosmogenic nuclide exposure dating can be used to date bedrock surfaces or sediments on river terraces. Over longer timescales, however, surfaces are seldom preserved well enough for exposure dating. Yet it is important to understand how river incision varies through time over millions of years.

Cosmogenic Nuclide Burial Dating

Cosmogenic nuclide burial dating measures the decay of cosmogenic nuclides after sediment has been buried. If sediment containing cosmogenic nuclides is buried so that it is shielded from secondary cosmic radiation, then the inherited cosmogenic nuclides decay over time according to eqn [3]

$$N(t) = N_{\text{inh}}(0)e^{-t_{\text{burial}}/\tau} \quad [3]$$

where t_{burial} is the time since burial and N_{inh} is the inherited cosmogenic nuclide concentration at the time of burial (Lal and Arnold, 1985). For a landscape eroding at steady state, N_{inh} can be determined using eqn [2]. Burial dating works exceptionally well with the cosmogenic nuclide pair ^{26}Al – ^{10}Be in quartz, because these nuclides are produced at an effectively constant ratio, and they decay at different rates subsequent to burial. By solving eqn [3] simultaneously for both ^{26}Al and ^{10}Be in the same sample of quartz, both the burial time and the paleo-erosion rate can be determined. The burial dating method is typically

limited to the past 5 million years, because ^{26}Al is usually undetectable beyond that time (Granger and Muzikar, 2001).

Burial dating requires that the sediment is shielded from secondary cosmic rays, including muons. The degree of shielding necessary to use this method depends on the age of the sediment being dated. For sediments older than a million years, burial depths of 10–20 m of sediment or rock are usually needed. Two situations that are appropriate for burial dating are thick alluvial terraces, where sediment packages are deposited in excess of 10 m, and caves, where sediment is deeply shielded underground.

Using Caves to Learn About River Incision Rates

Caves provide a nearly perfect scenario for burial dating because sediment washed into the cave entrance is instantly shielded beneath tens of meters of solid rock. Because caves are formed by flowing water, they can also provide information about the water table at the time of sediment deposition. Quartz sediment can be washed into caves either by a surface river that passes near a preexisting cave opening (Figure 3) or by a sinking river that carries sediment underground as the cave is being formed. In either case, the burial date of quartz in the cave indicates the last time that water flowed through the

Figure 3 River sediment deposited in caves such as this one above the New River, Virginia, can be dated with cosmogenic nuclides to infer long-term river incision rates.

passage. As a river cuts through bedrock, the cave is abandoned by flowing water. The fossil cave passage, together with its sediment, remains an indicator of when the river was at that particular elevation. In this way, caves are very similar to terraces; they both indicate past river levels and they both contain alluvial sediment. Caves sometimes offer an advantage over terraces, however, because the sediment within is shielded from weathering and erosion. Cave sediments can thus persist much longer than terrace sediments on the surface. Furthermore, burial in caves is instantaneous, whereas burial under younger terrace sediment may, in some cases, have the disadvantage of only partial burial for an initial period.

Example: The Siebenhengste–Hohgant Cave System and Glacial Valley Lowering in Switzerland

The Siebenhengste–Hohgant cave system in Switzerland has a relief of >1.3 km, stretching from the top of the mountains in the Alpine front to the bottom of the Aare glacial valley. The cave has developed in at least 14 distinct levels, each of which has been identified from the vadose–phreatic transition evident in the cave’s morphology. These cave levels formed primarily during interglacials, when water was undersaturated with respect to calcite, and they drained to the level of the adjacent valley floor. The cave levels therefore record the long-term incision of the Aare glacier. Most of the cave levels contain sediment that was washed into the system from the surface. By dating this sediment, we can learn about the rates of glacial valley incision.

Haeuselmann et al. (2007) dated 20 samples of quartz-bearing sediment from seven levels within the cave. Sediment ages range up to 4 million years, predating major glaciation in the Alps. The ages indicate gradual lowering of the valley floor, at a rate of about 120 m My^{-1} , until the middle Pleistocene. Beginning about 800 000 years ago, valley incision accelerated dramatically, lowering the valley floor by a kilometer. Incision rates increased by an order of magnitude. The reason for such rapid glacial valley incision remains unclear; perhaps rapid incision is a regional pattern due to climate change at the mid-Pleistocene transition (a global shift of glacial periodicity from 41 000 to 100 000 years), or alternatively, the signal could be limited to glacial dynamics in the Aare valley alone. In either case, the data show that the spectacular topography of the Aare glacial trough developed almost entirely over the past million years.

Additional Applications

There are many applications of cosmogenic nuclides in landscape evolution that have not been discussed here. For example, it is possible to use cosmogenic nuclides in buried sediments to infer not only the burial age, but also the paleo-erosion rate. For example, data from the Siebenhengste–Hohgant cave system, mentioned above, show that paleo-erosion rates in the Alpine front were about 100 m My^{-1} , in equilibrium with valley lowering rates in the Pliocene and early Pleistocene (Haeuselmann et al., 2007). Paleo-erosion rates in the Italian Apennines over the past million years also show steady erosion, in equilibrium with regional uplift rates (Cyr and Granger, 2008).

Another important application of cosmogenic nuclides is the discrimination of eroding versus noneroding areas beneath ice sheets and glaciers. It has long been suspected that cold-based glaciers, frozen to their beds, do not erode bedrock, while warm-based glaciers that slide over their beds are very effective at scouring bedrock. The degree of glacial erosion, though, has previously been difficult to measure. Cosmogenic nuclides provide a method for quantifying glacial erosion. This is because areas of bedrock that are eroded by less than a few meters retain cosmogenic nuclides generated prior to glaciation. Subsequent to deglaciation, these areas have an excess cosmogenic nuclide concentration relative to areas that are deeply scoured. This cosmogenic nuclide method has been used to demonstrate that significant areas of nonerosive ice existed in the Fennoscandian Ice Sheet (Fabel et al., 2002) as well as in northern Canada (e.g., Staiger et al., 2005).

Conclusion

The study of landscape evolution has historically been divided into two related but distinct approaches: denudation chronology and process geomorphology. Denudation chronology is concerned with establishing a sequence of events responsible for creating today’s landscape. These events may be associated with, for example, tectonic uplift, climate change, or drainage capture. However, process geomorphology is less concerned with the sequence of events in the past and instead focuses on the physical processes of how landscapes are changing today. Cosmogenic nuclides are contributing to both of these approaches. Measurements of erosion rates, soil production functions, and the influence of climate on erosion all increase our understanding of present-day processes that are shaping the landscape. However, river incision rates and paleo-erosion rates contribute more to understanding landscape history and denudation chronology. A fuller understanding of landscape evolution and the dynamic response of hillslopes to climate, tectonics, and land use change require both these historical and mechanistic perspectives.

Introduction

A number of important dating methods are used for studies in the Quaternary. Many of these subjects are discussed in detail in sections of this encyclopedia. The purpose of all of these methods is to estimate the age of the material of interest. Sometimes, the need is for the age determination to be very precise; in other cases, relative age or approximate age may be sufficient. Hence, the purpose of this article is to summarize those methods and discuss briefly their advantages and deficiencies. [Figure 1](#) summarizes the age ranges covered by different methods.

These methods can be subdivided into three main categories:

1. Radioactive nuclide methods
2. Radiative dosimetry methods and
3. Qualitative and comparative methods

Each of these sections is subdivided into the specific methods, and cross references to the more detailed articles that deal with these methods are also given.

Radioactive Nuclides

The most important collection of methods for Quaternary dating involve radioactive decay, or in some cases, the buildup of radioactive species. As radioactive nuclides will increase or decrease with time, we can use the concentration of the specific nuclide to estimate the age of the material ([Table 1](#)).

Radioactive species can be produced by two different kinds of nuclear processes: radioactive decay of a parent nuclide or

production by nuclear reactions as a result of exposure to cosmic or other radiation.

Radioactive Decay

For example, in the simple case of the study of a nuclide present in its maximum concentration at the creation of the material, such as radiocarbon dating, the number of ^{14}C atoms will decay with time, according to the radioactive decay equation, originally shown by Ernest Rutherford ([Dickin, 1995](#)):

$$dn/dt = -\lambda N \quad [1]$$

where the decay rate is proportional to the number of radioactive atoms present (N). The 'decay constant' λ defines the rate of decay. It is usual to refer to the 'half-life' of the radionuclide, which is the time for one-half of the remaining atoms to decay, which is related directly to the decay constant:

$$t_{1/2} = \frac{\ln 2}{\lambda} \quad [2]$$

If eqn [1] is integrated, within the limits $N=N_0$ at $t=0$ and $N=0$ at $t=\infty$, the result is a more common form:

$$\frac{N}{N_0} = e^{-\lambda t} \quad [3]$$

where N_0 is the number of atoms at time $t=0$ and N is the number of atoms at any time t .

In-Growth of a Radionuclide

In-growth of a radioactive species occurs when it is produced either from the decay of another nuclide or directly in the

Figure 1 Time scales of different Quaternary geochronology methods. Courtesy Scott Elias (Royal Holloway College, University of London).

Table 1 Radioactive Quaternary dating methods

Isotopic system	Parent nuclide or process	Half-life	Time scale	Material	References
^{14}C	$^{14}\text{C}(\text{n,p})\ ^{14}\text{N}$	5730 year	0–50 000 year	Organic material, carbonates	Taylor (1987)
^{230}Th	^{238}U and ^{234}U	75 200 year	1000–500 000 year	Carbonates	Schwarcz (1989)
^{210}Pb	U-series decay sequence	22.3 year	0–150 year	Fine-grained sediments	Olsson (1986)
U–He	U isotopes α -decay	Depends on parent nuclides	0–300 000 year	Tephra	Kohn et al. (2000)
^{137}Cs	U fission	30	After AD 1950	Fine-grained sediments	Pennington et al. (1973)
^{40}K – ^{40}Ar	^{40}K β -decay	1.25×10^9 year	10^4 – 10^9 year	K-bearing minerals, bones, tephra	McDougall and Harrison (1988)

sample. The latter example occurs often in the case of *in situ* cosmogenic nuclide studies.

An example of a process where the in-growth of a radionuclide is the ^{231}Th – ^{235}U system. In this case, ^{231}Pa increases with time due to the decay of the parent nuclides ^{235}U , so that (Ku, 1968):

$$N_{231} = N_{235}(1 - e^{-\lambda t}) \quad [4]$$

A more complex case occurs for ^{230}Th . In this case, ^{230}Th increases with time due to the decay of the parent nuclides ^{234}U , which is produced from ^{238}U decay (see U–Th section). Because the half-life of ^{234}U is very low compared to either the parent ^{238}U or daughter ^{230}Th , in principle, it should drop out of the equation. This equation would be correct if the intermediate daughter product of ^{238}U , ^{234}U , was in secular equilibrium with the ^{238}U (Ku, 2000). Hence, the amount of ^{230}Th produced is a product of the decay of both the excess ^{234}U and the ^{238}U . However, it is not and the result is a more complex equation, described in detail in the section on U–Th dating.

Radiocarbon Dating

As discussed in the sections on radiocarbon dating, this method is widely used for reconstructing the age of various kinds of carbon-containing materials. This involves a considerable amount of pretreatment chemistry (Figure 2). Here, organic or inorganic materials in equilibrium with the

Figure 2 Sample preparation chemistry at the University of Arizona AMS Laboratory.

production of ^{14}C in the atmosphere and its removal into the oceans, establish a consistent level of ^{14}C . When the animal or plant dies, it is removed from this quasi-equilibrium and so the level of ^{14}C decays according to eqn [1]. There are a vast number of applications of ^{14}C , which can be measured either by counting the decays of the radioactive ^{14}C or by direct atom counting by accelerator mass spectrometry (AMS). Most measurements these days are measured by AMS (see Figure 3). More details of ^{14}C dating are given in the sections by Cook

Figure 3 The 3 MV accelerator mass spectrometer at the University of Arizona.

and van der Plicht, who discuss decay counting of ^{14}C and Jull, who discusses AMS. Other chapters by van de Plicht and Burr discuss the causes of ^{14}C variations over time.

U-Series Methods

Studies of uranium-series nuclides (Wagner, 1995) rely on the extensive decay sequence in the uranium decay series. We can take some of these pairs such as ^{234}U – ^{238}U , ^{230}Th – ^{238}U , ^{231}Pa – ^{235}U , and ^{226}Ra – ^{230}Th as chronometers for measurements of time on various time scales, depending on the radioactive pair chosen (Ku, 2000). Problems can arise, such as where there is some initial ^{230}Th . Hence, calculations of the age must take into account if there is disequilibrium in the ^{238}U – ^{234}U system (Cohen, 2005). U-series nuclides have a wide variety of applications to dating of sediments, soil horizons, peat, bones, corals, and carbonates of all kinds.

Other Dating Methods Based on U-Series Decay

Although sometimes listed as a separate method, in U–He dating, one observes the in-growth of the He daughter product of U. This method is sometimes used for dating bones, mollusks, and corals (Wagner, 1995). Similarly, the U-daughter nuclide ^{210}Pb can be used for dating of sediments in the last ~200 year (Cohen, 2005; Wagner, 1995).

K–Ar Dating

The K–Ar method and its companion, the $^{40}\text{Ar}/^{39}\text{Ar}$ method, are based on the radioactive decay of ^{40}K to ^{40}Ar (Renne, this volume). ^{40}K undergoes a branching decay to both ^{40}Ar and ^{40}Ca , so it is important to revise the simple radioactive decay equation to take into account the decay via different processes. The ^{40}Ar – ^{39}Ar process is based on the same idea as that of the K–Ar method, except that neutron activation is used to estimate the amount of ^{39}K by activation to ^{39}Ar . The in-growth of ^{40}Ar is a variant of the in-growth eqn [4], since there is actually a branching decay to ^{40}Ca and ^{40}Ar from ^{40}K :

$$^{40}\text{Ar} = ^{40}\text{Ar}_{\text{initial}} + 0.105 ^{40}\text{K} (1 - e^{-\lambda t}) \quad [5]$$

where t is the age and 0.105 is the branching ratio to ^{40}Ar . K–Ar dating has many applications, particularly during the Quaternary to the dating of bones and tephra.

Cosmogenic Radionuclides

Similar equations to those for in-growth of a nuclide also apply to the case of the buildup of a cosmogenic radionuclide such as ^{10}Be :

$$N = \frac{P}{\lambda} (1 - e^{-\lambda t}) \quad [6]$$

Here, P is the production rate in atoms per year and λ is the decay constant (in years $^{-1}$). More complex scenarios can arise where the sample is buried and re-exposed. The application of cosmogenic nuclide for dating of Quaternary surfaces and deposits has increased dramatically in the past decade (Dickin, 1995; Fifield and Fink, 2010; Zreda and Phillips, 2000), as presented elsewhere in this volume.

In the case where the cosmogenically produced nuclide is stable, the number of atoms produced is simply $N = Pt$. There have been a number of studies of stable noble gas nuclides in various rock surfaces.

Postnuclear Tracers

The radionuclides produced as the result of anthropogenic nuclear activities can be used as tracers for recent processes. Nuclides such as ^{137}Cs , ^{90}Sr , and postbomb levels of ^{14}C can be used to date event horizons since AD 1950. These markers are often of great use in the study of recently deposited sediments and other materials. Recent sediment studies are often done in conjunction with in-growth of ^{210}Pb from U-series decay (Cohen, 2005).

Radiative Dosimetry Methods

Radiative dosimetry methods are basically studies by which we investigate the buildup of radiation damage. This is usually measured by studying some luminescence phenomenon. Common methods are thermoluminescence, optically stimulated luminescence, and electron spin resonance (ESR) techniques. The techniques rely on the production of radiation damage in the substrate (usually, a silicate mineral). When these solids are exposed to ionizing radiation, electron/hole pairs are formed and some of these become trapped in the solid.

The luminescence age appears simple enough and is constrained by the equation:

$$\text{Age} = \frac{\text{ED}}{\sum D}$$

where ED is the 'equivalent dose' (in units of grays, 1 Gy = 100 rad) and $\sum D$ is the sum of annual doses from α , β , γ and cosmic radiation (Forman, 2000). ED is determined in several different ways, including estimates of the chemical composition of radioactive sources in the sample, regeneration of an additional dose of the luminescence signal in the laboratory, and partial or total bleaching (i.e., removal of the luminescence signal by exposure to light).

Table 2 Nonradiometric Quaternary dating methods

<i>Technique</i>	<i>Process</i>	<i>Time scale</i>	<i>Material</i>	<i>References</i>
Fission-track dating	α -particle tracks in minerals	10^5 – 10^9 year	Tephtras, glass	Westgate and Naeser (1995)
Amino acid racemization	Rate of equilibration of D and L isomers of amino acids	10 – 10^6 year	Mollusks, ostracods, egg shells, some fine-grained sediments	Wehmiller and Miller (2000)
Thermoluminescence	Luminescence resulting from heating to rest electronic traps caused by radiation damage	100 – 10^6 year	Fine-grained quartz or feldspar in sediments	Aiken (1998)
Optically stimulated luminescence	Luminescence resulting from optical stimulation to rest electronic traps caused by radiation damage	100 – 10^6 year	Fine-grained quartz or feldspar in sediments	Stokes (1999)
Electron spin resonance	Intensity of ESR signal proportional to the number of radiation-damage electron traps	100 year–50 ky	Fine-grained quartz	Lee and Schwarcz (2000)
Varve chronologies	Annual varve deposits in sediment	Any age, up to 45 ka correlated with radiocarbon chronology	Fine-grained sediments	O'Sullivan (1983), Wohlfarth et al. (1993), and Hughen et al. (1996)
Paleomagnetism	Changes in magnetic intensity and direction	10^2 – 10^8 year	Fine-grained sediments and volcanics	Thompson and Oldfield (1986) and Verosub (1988)
Tephrochronology	Volcanic ash layers	Varies	Tephtras	Westgate and Naeser (1995)
Biostratigraphy	Correlation of similar macrofossils	Any age		

The main problem with luminescence methods is the number of possible complications which can arise due to the fact that the original sediment was not totally bleached by sunlight before the accumulation of the dose under study, or that later partial bleaching occurs, or there is an unexplained loss of the signal, called 'anomalous fading' (Wintle, 1973).

There are two main methods which use radiative dose: fission-track dating and luminescence methods, which include thermoluminescence and optically stimulated luminescence (Aiken, 1998). Another radiative dose method which can sometimes be used is the study of the buildup of electronic 'traps' by ESR dating (Lee and Schwarcz, 1993). All of these methods have limitations due to the necessity of accurately estimating the levels of the source of the radiation, usually α particles (from the decay of U) and sometimes γ radiation (Wagner, 1995). These topics are all discussed in various articles of this encyclopedia and the references listed in Table 2.

Amino Acid Racemization

The technique of amino acid racemization relies on the kinetics of changes in the symmetry of amino acid molecules (Miller and Brigham-Grette, 1989). As amino acids can have two different optically active isomers, there is one biologically preferred form (usually the L-form). After initial deposition, these amino acids react over time to approach an equal mixture of D and L isomers, which is called a racemic mixture (Figure 4). The decay rates of many of these reactions are known, although they are sensitive to changes in temperature, as are nearly all chemical reactions. Hence, in order to calculate an age from an amino acid composition, it is important

Figure 4 Exchange rates of amino acids at different temperatures. Reproduced from Hearty PS and Kaufman DS (2000) Whole-rock aminostratigraphy and Quaternary sea-level history of the Bahamas. *Quaternary Research* 54: 163–173.

to understand the reaction rates and the dependence of the reaction rates on temperature and other parameters (Wehmiller and Miller, 2000). The amino acid composition is usually expressed as the D/L ratio of the amino acid of interest. If the goal is absolute dating, it is usually necessary to compare the rates of change with some independent dating method such as ^{14}C . The method can also be used in conjunction with independent age estimates to measure temperature (Miller et al., 1997). Otherwise, serious errors can result, such as the very early age assignments of early humans in the New World, which were later shown to be in error by radiocarbon dating (Stafford et al., 1984).

Qualitative and Comparative Methods

There are several methods used for dating of geological materials and the methods rely on what are best described as relative or incremental techniques (Figure 5). These methods rely on various observations to estimate the passage of time:

- Deposition of regular additions of sediment on a cyclical fashion, called rhythmites. These are often called 'varves' if annually deposited. Lake varve chronologies were originally proposed as a dating technique by the Swedish geologist De Geer. These chronologies have also been proposed as ways to cross-correlate to other chronologies. In general, there is a degree of scepticism about some of these chronologies since it is difficult to establish a priori that the deposition is annual.
- Long varve chronologies have been established for marine sediments (e.g., Hughen, this volume) and these chronologies have been incorporated into some radiocarbon calibration schemes. These varved sediments in principle have the same problems as lake sediments, but in the case of the Cariaco Basin chronology (Hughen et al., 2004), there is good evidence that the annual deposition assumption can be taken as valid over certain parts of the time scale.
- Lichenometry. The incremental growth of certain lichen species has been used to estimate the age of a rock surface. The technique was pioneered by Bull (2000) who used measurements of the diameter of the largest lichens on surfaces as a way of estimating the age of the surface. This approach appeared to give approximate ages for some surfaces which could be confirmed by other methods.
- Dendrochronology. Trees produce annual growth rings and hence, the variation of the thickness of tree rings can be cross-correlated with established chronologies (Figure 6).

Figure 6 A Bristlecone pine from the White Mountains of California. Courtesy of the University of Arizona Tree Ring Laboratory.

In cases where a piece of wood can be dendrochronologically dated, results can be precise to a few years.

- Paleomagnetic dating. The remanent magnetization in magnetically susceptible materials in sediments and ceramics can sometimes be correlated with known geomagnetic fluctuations (Butler, 1992). Both the intensity of the geomagnetic field and its direction change with time (Cohen, 2005). The sequence of geomagnetic signals in a sediment sequence can then be used to estimate the age of the sequence.
- Correlation of isotopic signals is also an important method for Quaternary dating. The long record of $\delta^{18}\text{O}$ in ice cores and marine sediments is often used to cross-correlate between different marine and ice core records, and therefore establish definite time markers. An excellent example is the ability to cross-correlate dramatic changes in climate from glacial to interglacial, or a return to glacial-like conditions, such as the Younger Dryas event at about 13 000 years ago (Markgraf, 2001), through the oxygen-isotope record (Mayewski et al., 1997).
- Correlation of changes of flora and pollen can sometimes also be correlated between different sites in the same region or over wider areas (Bradbury, 2001).

Dendrochronology

Introduction

Dendrochronology is the science that deals with the dating and study of the annual growth increments, or tree rings, in woody trees and shrubs. When the radial growth of trees is affected by a common limiting factor, tree-ring variations are replicated across forest stands and cross-dating, or pattern matching, of these series can provide an accurate record of annual growth trends. These data can be used to date events or describe variations in environmental conditions. Due to the annual resolution and spatial breadth of tree-ring records, dendrochronological analyses provide both reliable and ubiquitous archives for dating past events and for paleoenvironmental reconstruction.

Origins and History

Early in the fifteenth century, Leonardo da Vinci noted the annual nature of tree rings, recognizing a relationship between the size of individual rings and precipitation (Stallings, 1937). The first recorded application of dendrochronology occurred in 1737 when Du Hamel and De Buffon observed a prominent frost-damaged tree ring in recently felled trees (Studhalter, 1955, 1956). By the mid-1800s, the ecological foundations of dendrochronology were established following Theodore Hartig's study of wood structures and annual tree-ring development (Schweingruber, 1988). By the end of the nineteenth century Hartig's son, Robert, had published papers on the anatomy and ecology of tree rings, using them to date hail events, frost years, and insect damage in trees (Schweingruber, 1988).

In 1904, astronomer Andrew Ellicott Douglass began examining the annual rings of Ponderosa pine trees in the Southwestern United States as a potential source for pre-instrumental climate records. He observed that narrow tree rings formed in very dry years over large geographical areas, and confirmed that cross-dating of tree-ring variability between sites could be used to assign calendar dates to individual tree rings (Douglass, 1909). By 1914 Douglass had developed a 500-year cross-dated tree-ring chronology and established a positive correlation between ring width and precipitation in the winter preceding growth (Douglass, 1914). His chronology was used to date wood samples from prehistoric pueblo sites in the American southwest and established dendrochronology as an effective dating tool (Dean, 1997).

Prior to pioneering the subfields of dendroclimatology and dendrohydrology, Schulman (1945) began working with Douglass to develop better methods of tree-ring analysis. In his quest to improve the length and sensitivity of tree-ring records,

Schulman (1954) discovered the oldest living trees in the world; the more than 4000-years-old bristlecone pines of the California White Mountains. His discovery was integral to the calibration of atmospheric ^{14}C records and set the foundation for radiocarbon dating methods (LaMarche and Harlan, 1973).

Working in Europe after World War II, German botanist Bruno Huber pioneered an ecological approach to dendrochronology. His discovery that the year-to-year variation in tree rings was not as pronounced in temperate species as it was in those from semiarid zones led to a more quantitative approach to tree-ring research. Huber developed a statistical test of similarity, the Gleichlaufigkeit (Eckstein and Pilcher, 1990; Huber, 1943), which remains an integral component of statistical cross-dating in European laboratories.

In the early 1960s, Hal Fritts established the basic physiology of radial tree growth by employing a dendrograph (Haasis, 1933) to measure the daily growth of tree rings. As detailed in his seminal publication *Tree Rings and Climate*, Fritts (1976) was able to describe many of the complex relationships between tree rings and climate and used these insights to provide annually resolved climate reconstructions for eastern and western North America (Fritts, 1991). Polge (1966) applied X-ray densitometry to the study of tree rings, showing that density records provided higher resolution dendroclimatic insights than did records developed from solely from annual ring-width increments (Lenz et al., 1976).

In the last 50 years, dendrochronology has evolved from a tool primarily employed to date monuments and archaeological pueblos, to a discipline with a variety of applications including studies of: the history and effects of pollution (Schweingruber, 1988); geological dating (Winchester and Harrison, 2000); earthquakes (Jacoby, et al., 1997); snow avalanches (Smith et al., 1994); glacier movement (Luckman and Villalba, 2001); volcanoes (Jones et al., 1995); river flooding (St George and Nielson, 2003); and insect life cycles (Swetnam and Lynch, 1993). In addition to the continued application of the techniques pioneered by Douglass, new analytical techniques (i.e., X-radiography, X-ray densitometry, neutron activation analysis) are providing insights into climate-induced morphological and chemical changes within tree rings and wood cells, and are being used to describe trace element and isotope signatures (Hughes, 2011; Kuniholm, 2001).

Biological Foundations

Tree-ring dating is possible due to the physiological behavior of trees growing in seasonal climates. In these environments

Figure 1 A cross-section from a young subalpine fir (*Abies amabilis*) tree illustrating the annual concentric ring pattern around the stem of tree. Highlighted are the annual ring width (RW), latewood (LW), and earlywood (EW) components.

radial tree growth occurs in annual increments, or 'tree rings,' whose anatomical structures vary in response to fluctuating environmental variables (Figure 1). Although there are differences between the anatomical structures of angiosperms and gymnosperms, both trees are commonly used in dendrochronology.

Radial tree growth occurs as vascular cambium cells divide. During the winter months cambium is dormant and cell production ceases until warmer and/or wetter spring conditions reactivate cambial activity (Fritts, 1976). Xylem cells formed at the beginning of the season, referred to as 'earlywood,' tend to be large and thin walled. With the onset of hotter and/or drier summer conditions cambial activity slows and smaller, thick-walled xylem ('latewood') cells are produced (Fritts, 1976). It is the marked difference between earlywood and latewood cells that make it possible to discern annual growth increments (Figure 2).

Although tree rings usually form every growing season, a tree may fail to develop an annual ring or the ring may be discontinuous around the circumference of the tree stem (i.e., a missing ring; Speer, 2010). Intra-annual growth bands, or false rings, are sometimes produced if seasonal growing conditions temporarily deteriorate (Hoffer and Tardif, 2009). False rings are usually easily detectible, as the transition from one cell type to another is gradual. In contrast, the resumption of earlywood cell production after winter dormancy produces a distinct boundary (Figure 2). Missing rings are best identified by cross-dating comparison with established tree-ring series.

Principles of Dendrochronology

Seven widely accepted principles govern the application of dendrochronology. While some are specific to dendrochronology, others have been borrowed and modified from other disciplines.

Uniformitarian Principle

The principle of uniformitarianism was proposed by James Hutton in 1785. In the context of dendrochronology, it

Figure 2 Cross-sectional view of tree rings from a mountain hemlock (*Tsuga mertensiana*) tree.

suggests that the physical and biological processes that link environmental conditions to variations in radial tree growth in the present are the same ones that existed in the past. This does not mean that past conditions were the same as present ones, but rather that tree growth was influenced in the same manner in the past as it is at present (Fritts, 1976). Hence, by understanding present climate–radial growth relationships, dendrochronologists are able to reconstruct paleoenvironmental records from tree-ring data.

Principle of Limiting Factors

Annual tree-ring growth cannot proceed faster than permitted by the most limiting environmental factor (Fritts, 1976). For instance, in arid and semiarid regions, a lack of precipitation is often limiting and the annual radial increment is a direct function of the quantity of precipitation. Other limiting factors include air temperature, snowpack, and nonclimatic parameters such as soil condition or insect infestation. This principle is central to dendrochronological research in that tree rings may be cross-dated only if one or more environmental factors becomes significantly limiting, persists long enough, and acts over a wide enough geographical area to cause widespread common patterns of ring width variation.

Principle of Aggregate Tree Growth

According to this principle, tree-ring growth is an aggregate of several factors. In a simplified linear model of radial growth Cook (1987) notes that:

$$R_t = A_t + C_t + D1_t + D2_t + E_t$$

where the observed tree-ring width (R) in any one year (subscript t) is a factor of: age-related growth trends (A); the influence of climate (C); the pulse of a localized disturbance factor

Figure 3 Illustration of effects of the principles of ecological amplitude and site selection. Shown is the radial growth response of trees to limiting environmental factors under different site conditions. The top ring-width pattern (a) is from a tree found growing near its limit and exhibiting variable ring width patterns as a result of climatic stress. The sample below, (b), is from a tree near the center of its ecological range and not limited by environmental factors. As a result, the tree is not stressed and is producing complacent tree rings with little variability.

(endogenous disturbance, i.e., blowdown) (D1); stand-wide disturbance factors (exogenous disturbance, i.e., fire) (D2); and unexplained year-to-year variability not accounted for by these variables (E). To maximize the desired growth component (signal), the other factors (noise) should be minimized. For instance, to highlight a climate signal age-related growth trends must be removed (see *Standardization*), and trees and sites selected to minimize the influence of internal and external ecological processes on tree growth (see section ‘*Principle of Site Selection*’).

Principle of Ecological Amplitude

Tree-ring growth is particularly sensitive to environmental factors at the altitudinal and latitudinal limits of a species’ range (Figure 3). For example, growth is frequently restricted by average summer air temperature in high-mountain and high-latitude settings (Luckman and Wilson, 2005).

Principle of Site Selection

Tree-ring-width series that are highly variable and controlled by a limiting environmental factor can be selected for based on site-specific characteristics. For example, trees found growing on bare rocky outcrops are often sensitive to drought conditions. Conversely, trees growing in mesic environments are usually characterized by complacent (unvarying) growth trends (Figure 3).

Principle of Cross-Dating

Cross-dating procedures ensure that individual tree rings are assigned an exact year of formation. Cross-dating provides a means to date floating tree-ring series and to develop tree-ring chronologies that extend back beyond the age of living trees. Undated wood samples can be assigned ages by cross-dating to chronologies of known age (Figure 4). For instance, the date when a tree died can be determined by matching its ring patterns with those within a chronology developed from living trees and spanning, at least in part, the same interval of time (Figure 4).

Principle of Replication

An environmental signal of interest can be maximized, and the amount of ‘noise’ minimized, by sampling more than one stem radius per tree, more than one tree per site, and/or several sites in a region (Cook, 1987; Fritts, 1976). Cross-dating samples from multiple trees minimizes the likelihood that missing or false rings from individual trees will be incorporated into a chronology. Obtaining more than one sample per tree reduces the amount of ‘intratree variability,’ or the nondesirable environmental signal particular to a given tree.

Dendrochronological Methodologies

The primary objective in developing tree-ring chronologies is to establish stationary time series that are directly comparable and appropriate for statistical analysis (Fritts, 1976). Following the collection of tree-ring samples (Speer, 2010) chronology development generally follows a five-step procedure:

(i) *Sample preparation*: Increment cores are normally glued to slotted mounting boards. The surface of the cores are then sanded and polished at increasingly finer grits until the annual ring boundaries are clearly visible. If necessary, stem cross-sections (‘cookies’) are glued to preserve their structural integrity and are then similarly polished.

(ii) *Measurement*: Assessment of annual tree-ring increments was originally undertaken using manual (Stokes and Smiley, 1968), or more recently electronic (Cropper, 1979), skeleton plotting. According to this method the widths of unusually narrow and wide rings are represented by bars of varying length. Skeleton plotting is still commonly used for basic assessments of tree growth (Brookhouse, 2006; Pelfini and Santilli, 2008; Wils et al., 2009).

Numerous instruments are now commercially available to measure annual tree-ring parameters (Maxwell et al., 2011). These include widely employed plot/sliding linear-encoding measurement stages equipped with either high powered ocular microscopes or video cameras connected to a microscope. The latter display high-resolution images on computer monitors that allow for measurement accuracies of 0.001 mm. Semi-automated analysis systems employ high-resolution scanners to capture tree-ring images that are used to demarcate anatomical tree-ring boundaries. An advantage of the latter system is

Figure 4 Illustration of how a calendar date for the growth rings of an undated wood sample can be established by cross-dating with a dated living chronology. By anchoring floating chronologies to the living chronology, it is possible to determine when a sample was killed and to extend the duration of a tree-ring chronology.

that measurement pathways can be edited and saved as image files that can be revisited during the cross-dating process.

X-ray densitometry provides the opportunity to delineate and measure intra-annual tree-ring parameters, characteristics that are valuable for describing subannual relationships between variables such as earlywood/latewood density and seasonal environmental conditions (Cleaveland, 1986; D'Arrigo et al., 1992; Robertson and Jozsa, 1988; Schweingruber et al., 1978; Zhang, 2007). More recently the dendrochronological attributes of wood microstructures have been explored (Gureyev and Evans, 1997). High-precision assessments of annual to subannual variations in density (Evans et al., 2000; Robertson and Jozsa, 1988), microfibril angle (Sarén et al., 2004), cell wall mass (Silkin and Kirdyanov, 2003), and cell dimensions (Wood et al., 2009) are providing innovative insights into the role of climate in wood anatomy.

Differentiated image brightness variables also provide a measure of wood fiber features. Reflected-light imaging techniques, such as minimum blue intensity, provide proxy density measurements useful for developing paleoclimate records (Campbell et al., 2007, 2011; Sheppard et al., 1996). Similar approaches have successfully linked wood structure characteristics to specific disturbance incidents such as flooding (Yanosky and Robinove, 1986).

Measurement of annual variations in stable carbon, oxygen, and hydrogen isotopes in tree rings have been correlated to climate and climate-related parameters (i.e., soil moisture, summer irradiance, and air temperature) to provide both annual (McCarroll and Loader, 2004; Schleser et al., 1999) and intra-annual (Helle and Schleser, 2003; Porté and Loustau,

2001) insights useful for paleoclimatic reconstruction. Recent methodological advances in sample processing have substantially reduced the costs of isotopic analyses, making them increasingly attractive for application in dendrochronological research (McCarroll and Loader, 2004).

(iii) *Cross-dating*: A pattern-matching methodology used to assign dates to individual tree-ring chronologies. Absolute dating is possible when the age of at least one cross-dated sample is known (i.e., taken from a living tree). The presence of bark on a sample confirms that the last year of growth is present (Baillie, 1982). Series of unknown age are cross-dated by matching annual tree-ring parameters to those within a dated series (Figure 4). Cross-dating serves as a check for establishing measurement errors, or for recognizing the presence of false or missing rings (Stokes and Smiley, 1968). The application of quality checking software programs, such as COFECHA (Holmes, 1983) and CDendro (Larsson, 2003), provides a statistical measure of cross-dating quality.

(iv) *Standardization*: Annual tree rings and their anatomical characteristics typically vary in response to one or more limiting growth factors, as well as to traits such as tree age, stem height above the ground, site-specific characteristics, and general productivity (Fritts, 1976). To isolate the proportion of annual growth that is controlled by the limiting factor, the impact of these external parameters is statistically removed by standardizing and transforming each variable to an index (Fritts, 1976). The application of standardization procedures requires careful consideration of the morphological properties of individual tree-ring series and the statistical analyses to be performed (Cook and Kairiukstis, 1990; Speer, 2010).

(v) *Master chronology development*: Accomplished by combining transformed time series into dimensionless, site-specific, tree-ring-width indices (Cook and Holmes, 1986; Speer, 2010). A master chronology is considered representative of the tree growth trends at a site, and can subsequently be correlated to the environmental parameters limiting that growth.

Concluding Remarks

The broad geographical distribution of trees, and the annual to subannual resolution of their annual growth rings in temperate latitudes, has permitted dendrochronological methodologies to be employed in a wide array of applications. Towner (2013) illustrates how dendroarchaeological studies continue to allow researchers to understand the impact of paleoenvironments on human activity. In paleoenvironmental studies, Luckman (2013) describes how dendroclimatologists have used tree rings to reconstruct millennia-long records of temperature, precipitation, and related variables such as streamflow at various spatial and temporal scales. Gärtner and Heinrich (2013) provide examples of how tree rings afford an annually resolved methodology for documenting prehistorical geomorphic activity and landform dynamics; long-term records that provide critical insights for modeling future landscape responses to shifting climates. The accelerating retreat of glaciers in many settings is exposing the remains of subfossil trees that dendroglaciologists are examining to date and reconstruct Holocene glacier activity. As Coulthard and Smith (2013) describe, tree rings are also providing detailed multicentury mass balance records useful for understanding the long-term glaciological response of glaciers to changing climates. Future dendrochronological research opportunities include the development of new measurement approaches and instruments, exploring multiproxy dendrochronological assessments of climate and stand disturbance, giving focused attention to trees growing in tropical latitudes (Speer, 2010), and evaluating the physiology of nonstationary radial growth responses to variable climates (Esper and Frank, 2009).

Dendroclimatology

Introduction

Tree-ring series provide the most widely distributed and easily accessible archive of annually resolved proxy climate data. In regions with well-defined seasonal growth, the annual growth rings of trees provide both chronological control and a continuous time series of proxy environmental variables. The year-to-year variability of the physical (e.g., width and density) and chemical properties of these annual rings provides potential proxies for the environmental factors that influence tree growth. Dendroclimatology can be defined simply as 'the science that uses tree rings to study present climate and reconstruct past climate' (Grissino-Meyer, n.d.) and during the past 30 years has become a major tool in the reconstruction of climates of the past millennium in many areas of the world. A detailed review of recent developments in the field is given in Hughes et al. (2011a,b).

Basic Principles and Methods

The process of matching patterns of tree-ring width between series (cross-dating) is one of the fundamentals of dendrochronology. It is used to verify the dating of tree-ring series and, in some cases, to demonstrate that the series are annual. For cross-dating to be successful, the ring parameters must vary synchronously among series, reflecting a common response to an external variable. Tree growth is influenced by many factors, but often only one is strongly and consistently limiting. Successful dendroclimatological studies target sampling sites where a single climate parameter is, or is expected to be, the limiting factor of growth and therefore the primary control of interannual variability in ring width. The presence and strength of the common signal between tree-ring series within a site is a measure of the degree of climate control of growth: correlation between tree-ring series from different sites across a broad area almost inevitably reflects a common climate control, as no other controlling factors vary systematically at these spatial scales. Therefore successful cross-dating usually establishes the presence of a climate signal in tree-ring series.

Trees growing at their range limits are often the most sensitive to climate variability, whereas trees in mid-range or interior forest sites may show 'complacent' ring-width series with little interannual variability. Classically, latitudinal and altitudinal treeline sites are most sensitive to temperature variations, whereas lower treeline and/or forest border sites are moisture sensitive; however, there are exceptions. Bald cypress trees growing in swamps in the southeastern United States are sensitive to the water level (and therefore precipitation), and growth at many treeline sites in arid mountains is sensitive to both precipitation and temperatures (e.g., Bristlecone pines (*Pinus aristata* and *P. longaeva*)). The key to dendroclimate research is careful site selection, as the limiting factor to growth

can also vary based on microsite considerations. Dendroclimate studies further assume that the growth-limiting factor at a site does not change over time, and therefore contemporary tree-ring climate relationships can be used to reconstruct past climate conditions.

Models of cambial processes in trees have recently been developed and used to simulate tree-ring widths and cell development in response to selected climatic and site variables (see Vaganov et al., 2011 for a review). However, most dendroclimate studies have been carried out using ring-width data. Annual tree rings can be divided into earlywood (larger, thin-walled cells) and latewood (smaller cells with thicker walls). The earlywood-latewood transition is usually gradational but the latewood-earlywood boundary is sharply defined and marks the end of the growth year. Traditionally, ring width is the primary variable used for dendroclimate work, but more recently other variables such as earlywood width or latewood width have been successfully used for seasonal precipitation reconstructions (e.g., Meko and Baisan, 2001; Stahle et al., 2000). Tree-ring densitometry was initially developed by Hubert Polge (1966) in France and applied to climate studies by Parker and Henschel (1971). Traditionally, precise thin sections are cut from the cores, x-rayed, and the negatives scanned with a high-resolution densitometer to produce a continuous density trace orthogonal to the rings. Several ring-width and density variables can be obtained from these scans. Maximum latewood density (MXD) reflects the thickening of cell walls at the end of the growing season and therefore represents a narrower climatic window than more traditional ring-width parameters (Schweingruber et al., 1978). MXD in northern conifers is very strongly related to summer half-year temperatures and has been used in several important temperature reconstructions. Recently non-film-based densitometric systems have been developed for tree-ring studies (see <http://www.geog.uvic.ca/uvtr/uvtr.htm>), and other approaches such as blue intensity measures have been developed as alternates (Campbell et al., 2007; McCarroll et al., 2010).

Chronology Development

The fundamental data in dendroclimatology are tree-ring chronologies – average series of, for example, tree-ring widths from a stand or sample site of a single species growing under similar conditions. Individual chronologies usually consist of paired radii from at least 10–20 erect trees without growth anomalies. The age assigned to each measured ring is verified by the process of cross-dating the series against each other and/or reference sequences (matching ring patterns either visually or by computer software) to ensure secure dating and to check for the presence of 'false' or locally absent rings. Prior to averaging, each tree-ring series is converted to indices by removing low-frequency age-related trends. This 'standardization' process is

usually accomplished by dividing the measured ring parameter for each year by values derived from a theoretical curve (commonly a negative exponential or linear regression) that converts these data to a stationary series with a mean of 1 and similar variance throughout the series. This approach ensures that each sample contributes equally to the average series by removing differences in mean ring widths between series (e.g., wider rings in relatively young trees, narrower rings in older trees). Several approaches to standardization are available (see, e.g., Cook and Briffa, 1990; Fritts, 1976) and are the subject of continuing discussion because standardization can modify the common (climate) signal retained within these chronologies. This is a significant concern in the construction of long chronologies from overlapping cross-dated segments of living and subfossil material where standardization may remove climatically related low-frequency trends from tree-ring series. Recent studies indicate that the frequencies retained may be as little as one-third of the mean segment length in the chronology (the 'segment length curse', Cook et al., 1995). Special techniques have been developed to try and retain this low frequency signal (see Briffa and Melvin, 2011; Briffa et al., 2001; Esper et al., 2003a,b).

In any chronology, sample depth decreases further back in time as there are fewer older trees. Expressed population signal (EPS) is an objective measure of signal strength, based on intercore correlation and sample size, that can be used to identify those parts of a chronology (usually the oldest sectors) where signal strength falls below acceptable levels. Wigley et al. (1984) suggest that an EPS value of 0.85 is a reasonable threshold for adequate signal strength. The effective sample size for chronology development depends on the strength of the common signal between these series; for example, at sites where intercore correlation averages approximately 0.6, four or five trees may provide adequate signal strength but over 20 trees would be needed at sites with mean intercorrelation values of approximately 0.2 (Briffa and Jones, 1990).

Reconstruction of Climate Variables

Identification and capture of the climate signal in tree-ring series is accomplished through the process of sampling and chronology development. Isolation of the climate signal is best described by the 'Conceptual Linear Aggregate Model' developed by Cook (1990) following Graybill (1982). In this model, the variation in ring width can be decomposed into several components, namely, $R_t = A_t + C_t + \delta D1_t + \delta D2_t + E_t$. In this expression, R_t is the ring-width series, A_t is the age-size related trend of ring width, C_t is the climatically related environmental signal, $\delta D1_t$ and $\delta D2_t$ are local ($D1$) or stand-wide ($D2$) nonclimatic disturbances, and E_t is unexplained year-to-year variability (Cook, 1990). Ideally, the E term is random and minor, and can be minimized by averaging sufficient tree-ring series. The disturbance effects may be present or absent and can be avoided by examination of the individual series ($D1$), by careful site selection prior to sampling ($D2$), or by comparison of the record with that from adjacent undisturbed sites. The age-related term is removed by standardization. Averaging of the indexed tree-ring series emphasizes the common climate signal, and conceptually the equation simplifies to $R_t \approx C_t$.

Identification of the climate signal in tree-ring series requires calibration against instrumental climate data that overlap part of the tree-ring series. These climate data should be spatially representative and homogeneous (i.e., high-quality series that are continuous, complete, and corrected for any changes in station location, instrumentation, measurement practices, etc.). They may be single-station data or aggregated at appropriate spatial scales that vary with the parameter being investigated. Although proximal sites are ideal, proximity is more significant for precipitation than temperature data because of the greater spatial coherence of temperature fields (Jones and Thompson, 2003). Exploratory response function or correlation analyses are used to identify the strongest relationships between tree growth and a wide range of monthly, seasonal, or annual temperature or precipitation variables for periods up to 2 years prior to the growth year (see Fritts, 1976). Subsequent analyses develop a transfer function model between the most significantly related climate variable (annual precipitation, summer temperatures, spring precipitation, etc.) and a series of candidate tree-ring-derived variables (ring width, ring width of the previous year, maximum density, etc.). The tree-ring data are then entered into the model to reconstruct or hindcast the climate variable. Dendroclimate reconstructions are unique in that they are routinely verified against data withheld from the initial calibration and error terms can be applied to these reconstructions (Cook and Kairiukstis, 1990). Ideally, if the calibration dataset is long, then split-period verification is used. Calibration (transfer function development) is carried out using one-half of the data and the predicted values compared ('verification') against the data withheld from calibration. Subsequently, the procedure is reversed and, if these results are satisfactory (i.e., the relationship is time-stable) and pass a series of statistical tests, the entire joint dataset is used to derive the transfer function used to reconstruct the climate variable for the entire chronology. Reconstructions are generally modeled linearly using regression-based procedures. For short calibration datasets, the 'leave out one' procedure (Gordon, 1982) may be used. In addition to simple reconstructions for individual sites, extensive single- or multispecies chronology networks allow the reconstruction of temperature, precipitation, or atmospheric fields over large areas. An interesting discussion of correlation and response functions and the derivation of chronology statistics is given in Cook and Pederson (2011).

Historical Development

Although there are scattered examples from Europe of tree-ring counting dating back several hundred years (see Schweingruber, 1988), the 'father' of dendrochronology is generally considered to be the astronomer A.E. Douglass who first developed the principles of cross-dating and built chronologies based on drought-sensitive trees from the American Southwest, ultimately using them to date archaeological sites. In 1937, he established the Laboratory of Tree-Ring Research (LTRR) in Tucson, Arizona, which was the dominant center for dendrochronology in the Americas for the next 50 years. Edmund Schulman made significant early developments in dendroclimate research at Tucson during the 1930–50s,

'discovering' the ancient Bristlecone Pines in the White Mountains that were used for the first calibration of ^{14}C dating. The oldest yet known pine was 4862 years old, and the oldest presently living tree is >4765 years. Schulman also carried out pioneer reconnaissance studies of trees in similar semiarid environments in Canada, Argentina, Chile, and Mexico. In Europe, Bruno Huber took up Douglass' ideas and with his students undertook studies of trees within the temperate mountains of Europe between the late 1930s and 1960s. Modern quantitative dendroclimatology, while drawing on these earlier studies, stems largely from the classic work of Hal Fritts (1976) at LTRR, who documented many of the basic principles of the science and led the application of computing techniques and statistics to tree-ring analysis which revolutionized the discipline. Much of the classic work from Tucson focused on ring-width studies of arid land conifers. However, in the last 35 years, the research field has expanded rapidly and diversified with the development of new laboratories, techniques, and research centers (see listings in Grissino-Meyer, n.d.), engendered in part by the climate change debate and the need for long, annually resolved proxy climate records (Hughes, 2002, 2011). Dendroclimatology is now applied to a broad range of species and environments that cover the globe from forest tundra at 72°N in Siberia to scrubby rainforest at 56°S at Cape Horn, or from sea level in Alaska to higher than 4900 m on the Bolivian Altiplano.

Although dendroclimatology has typically utilized physical measures of tree-ring characteristics, increasing attention has been paid to the study of stable isotopes (mainly $\delta^{13}\text{C}$, $\delta^{18}\text{O}$ and δD) in tree rings over the last 20 years. Gagen et al. (2011) provide a recent review of this work, noting, in particular, that isotopic series are seen to have higher signal strength, no long-term age-related trends, and potentially different climate signals than traditional width and density variables, especially in tropical trees that lack annual rings.

Recognition of the increasing utility of tree-ring records for paleoclimate study and the expanding scales of investigation created the need for the archiving and exchange of data and the development of an easily accessible international database with standard protocols for format. The International Tree-Ring Data Bank (ITRDB) was founded in 1974 and has been housed at the NOAA Paleoclimatology Data Center in Boulder, Colorado, USA, since 1992. Initially based on the LTRR collections, it is now a truly global (if unevenly distributed) data base that presently holds over 2000 chronologies from over 150 species on 6 continents. These data are freely accessible online at www.ncdc.noaa.gov/paleo/paleo.html together with statistical programs for the analysis of tree-ring data from LTRR and other laboratories. The website also provides access to many tree-ring-based temperature and precipitation reconstructions plus links to other collections of tree-ring data.

Applications of Dendroclimatology

Dendroclimatological techniques have been used to reconstruct a wide range of paleoclimate variables that have progressively expanded from local to regional and continental scales. In providing examples of these applications, this article proceeds from relatively simple single-chronology examples to the

results from large-scale networks. For a more comprehensive review, see Hughes et al. (2011a,b).

Single-Site Reconstructions

The earliest recognition of climate sensitivity in North American tree rings came from the American Southwest, where Douglass first exploited the relationships between narrow rings and precipitation to infer major droughts based on tree-ring records from precipitation-sensitive trees. Drought-sensitive conifers show some of the strongest relationships with ring-width values (Figure 1). Many reconstructions have been developed from such relationships to show seasonal or annual precipitation totals. In some cases where there is more than one 'wet season,' seasonal precipitation amounts may be reconstructed separately based on differences between the earlywood, latewood, or total ring chronologies. For example, latewood widths from Douglas fir (*Pseudotsuga menziesii*) in Central Mexico are strongly correlated with the April–June rainfall, which is critical for the rain-fed maize crop. Therefore, the reconstruction of maize yields in Figure 2 is essentially a precipitation reconstruction in which the major droughts are verified by historical records (Therrell et al., 2006). Drought magnitude and frequency can also be determined from reconstructions of climate indices such as the Palmer Drought Severity Index (PDSI).

Reconstructions of temperature from ring-width data are usually for summer season, or annual values. Jacoby and Cook (1981) were the first to demonstrate strong linear relationships between spruce ring widths and June–July temperatures for a site in the central Yukon (65°N). This record shows strong low-frequency variability and, together with 19 other treeline chronologies from North American, Scandinavia, and Russian treelines, provided one of the early reconstructions of a Northern Hemisphere temperature record (D'Arrigo and Jacoby, 1993). Significant summer temperature reconstructions have also been developed for northern conifers based on MXD data or combined ring-width and MXD data (see for example, Luckman and Wilson, 2005).

Routinely recoverable tree-ring records in many parts of the world are less than 2–300 years, as heart rot, fire, or other disturbances limit the age of trees. Long, climate-sensitive chronologies are therefore of particular importance, and attention has been given to sites with long-lived species, well-preserved subfossil wood, or both. Many of these chronologies come from the range limits of species, particularly at Northern Hemisphere treelines with old slow-growing trees and/or good preservation of wood at dry or cold sites (Briffa, 2000). The greatest concentration of these long chronologies is in the SW United States (Hughes and Graumlich, 1996) but millennial chronologies are now developed in Northern Europe (see Briffa and Matthews, 2002), Canada (e.g., Luckman and Wilson, 2005), Mexico (Stahle et al., 2011), the Alps (Büntgen et al., 2005), and Asia (e.g., D'Arrigo et al., 2001; Esper et al., 2003a,b). These long chronologies, combined with other high-resolution proxy climate series, are primary inputs for several Northern Hemisphere annual or summer temperature reconstructions (e.g., Briffa et al., 2004; Esper et al., 2002; Mann et al., 1999) for the last millennium. Although these show a fairly similar pattern for the last 3–400 years (Figure 3), there

Figure 1 Actual and reconstructed precipitation for Santiago, Chile, 1866–2000, based on ring widths of *Austrocedrus chilensis* (J.A. Boninsegna, personal communication). The adjusted r^2 value is 0.54.

Figure 2 Reconstructed crop yield for central Mexico from 1480 to 2000 based on latewood ring width of Douglas fir growing at Cuauhtemoc la Frangua, Mexico. Maize cultivation is 'rain-fed' and the yield is strongly correlated with April–June rainfall. Dating for the major droughts is based on documentary records. Reproduced from Therrell et al. (2006).

are differences in the earlier records related to the relatively sparse and unevenly distributed sample base and the methods of standardization used (see Rutherford et al., 2005). This situation should improve as more chronologies and a more widespread distribution of long chronologies become available; however, it is clear from reconstructions of the last few hundred years that, although some variations may be globally

synchronous, for example, those forced by solar activity, there is considerably spatial variability at all timescales.

Currently, there are fewer long chronologies (and related temperature reconstructions) from the Southern Hemisphere, in part because of the restricted land area. However, recent work has significantly increased coverage in Tasmania, New Zealand, and Southern South America (see Boninsegna et al.,

Figure 3 Comparison of three millennial-length Northern Hemisphere (NH) temperature reconstructions based exclusively on tree-ring data and standardized to emphasize low-frequency variance. The reconstructions are Briffa (2000), Esper et al. (2002), and D'Arrigo et al. (2006a,b,c) and are scaled to NH land temperatures (R. Wilson, personal communication).

2009; Roig et al., 2010). Millennial and multimillennial temperature reconstructions have been made from the Huon Pine in Tasmania (Cook et al., 2000), silver pine in New Zealand (Cook et al., 2002a,b) and from *Fitzroya cupressoides* (Alerce) in Chile and Argentina (Lara and Villalba, 1993; Lara et al., 2000). Precipitation reconstructions 6–800 years long are now available using *Austrocedrus chilensis* in Chile (Christie et al., 2010; Le Quesne et al., 2006).

Tree-Ring Networks

The widespread distribution of suitable sites for dendroclimatology has resulted in considerable effort to build single or multichronology networks to reconstruct spatial patterns of climate variability. Reconstructions based on multiple sites also reduce the influence of local site factors and enhance the common regional signal in the reconstructed record. The first explicit attempt was made by Harold Fritts (1976, 1991) and colleagues who used a network of 65 moisture-sensitive ring-width chronologies to reconstruct spatial patterns of temperature, precipitation, and atmospheric pressure across western North America. In a parallel endeavor, Fritz Schweingruber and colleagues built a circumpolar network of over 387 MXD and ring-width chronologies (Schweingruber and Briffa, 1996), which permit the development of hemispheric-scale warm season temperature histories and the study of spatial patterns over the last 300 years. Assigning 303 chronologies from this network to 92, $5^\circ \times 5^\circ$ temperature grid boxes has yielded maps of circumpolar summer temperature patterns for each year since 1600 (Figure 4) (Briffa et al., 2002). The composite Northern Hemisphere (20–70° N) series developed from these data clearly shows the global impact of major volcanic eruptions on summer temperatures over the last 600 years (Figure 5). Cool and/or wet summers, following major volcanic eruptions, have poorly developed latewood and are characterized by 'light' rings in MXD chronologies. Decreased

temperatures following major volcanic activity may also be inferred by the presence of 'frost rings' which show cell disruption due to freezing at certain high-elevation sites (LaMarche and Hirschboeck, 1984). The chronological precision of these tree-ring dates is comparable to documentary sources and superior to that available from ice cores or radiocarbon dating for events prior to the historic record, enabling tentative calendar dates to be ascribed to major volcanic or possibly cometary impact events in the last 2–3000 years (Baillie, 1996; Grudd et al., 2000).

The major recent developments using networks of tree-ring data have targeted drought-sensitive records, usually presented in a gridded data base. Expansion of the Fritts network, incorporating results from many investigators, led to the development of a network of 155 PDSI reconstructions for a 2° latitude by 3° longitude grid that essentially covered the coterminous United States (Cook et al., 1999). This was subsequently expanded to 286 grid points ($2.5^\circ \times 2.5^\circ$) that cover most of North America from the Yukon to Yucatan (Cook et al., 2004). These reconstructions provide a powerful tool for the analysis of hydroclimate variability across North America (Figures 6 and 7) and exploration of the spatial extent and duration of drought, placing twentieth-century records in a long-term context (Fye et al., 2003). In the western United States, this new reconstruction has 68 grid squares with records that extend back to AD 800, showing the extent of significant droughts in the twelfth and thirteenth centuries and even a major eighth-century drought that had important impacts on the cultural history in pre-Hispanic America (Acuna-Soto et al., 2005; Stahle and Dean, 2011). The North American Drought Atlas derived from these data is freely accessible (<http://www.ncdc.noaa.gov/paleo/pdsi.html>) and provides a useful tool for exploratory analyses that demonstrate potential influence of selected atmospheric circulation patterns on precipitation and growth of tree-rings across North America (e.g., St. George et al., 2009). Cook et al. (2010) have published a similar gridded PDSI data base (also available from the NOAA paleoclimate website) covering a large area in SE Asia which is

Figure 4 Estimated April–September temperature anomalies for the land area between 20° and 70° N, smoothed with a 25-year filter and based on MXD. The lower diagram shows values of the volcanic explosivity index. Eruptions with uncertain dating are indicated by question marks. Note the strong cooling trend reconstructed for the late twentieth century, reflecting a loss of temperature signal in these data. Reproduced from Briffa KR, Osborn TJ, and Schweingruber FH (2004) Large-scale temperature inferences from tree rings: A review. *Global and Planetary Change* 40: 11–26.

Figure 5 Mean April–September gridded temperature anomalies for 1816 and 1828 estimated from MXD tree-ring data. These are two of the most extreme years in the nineteenth century (1816 follows the Tambora eruption). Note the regional differences in temperatures (K. Briffa, personal communication, see Briffa et al., 2002, 2004).

affected by the Asian Monsoon. This database used 328 chronologies to develop data for 534, $2.5^\circ \times 2.5^\circ$ grid squares over the period from 1300 to 2005 and provides the first long-term picture of monsoonal variability prior to the instrumental climate record. Recently, Neukom et al. (2010a,b) have used new tree-ring collections and other proxy data to reconstruct separate summer and winter surface air temperature and precipitation fields for a $0.5^\circ \times 0.5^\circ$ grid that covers southern

($>20^\circ$ S) South America and provides records between 300 and 900 years long. Collectively, these gridded reconstructions provide annually resolved data on major elements of the global climate system and its long-term variability, particularly for the circum-Pacific region. These studies are critical to documenting whether the decadal and longer variability seen in available instrumental records is characteristic of the long-term behavior of the climate system.

Figure 6 Comparison of instrumental and reconstructed PDSI data for the United States during the 'dustbowl' drought of 1929–1940. Reproduced from Fye FK, Stahle DW, and Cook ER (2003) Paleoclimate Analogs to 20th century moisture regimes across the US. *Bulletin of the American Meteorological Society* 84: 901–909.

Figure 7 Coverage of the $2.5^\circ \times 2.5^\circ$ gridded PDSI dataset for North America based on tree-ring data. The diagram on the right shows the average reconstructed PDSI for the major drought between 1560 and 1589 (David Stahle, personal communication; see Cook et al., 2004).

Noncontiguous sets of tree-ring data have been assembled to examine spatial patterns and teleconnections associated with large-scale atmospheric phenomena. This is the basis for the field of 'synoptic dendroclimatology,' which examines climate variability through reconstructing changes in the atmospheric circulation patterns that control temperature and precipitation fields (Hirschboeck et al., 1996) and attempts to reconstruct climate fields from limited proxy data (Evans et al., 2001). The strong relationships between winter precipitation, El Niño Southern Oscillation (ENSO), and ring width in the SW United States and adjacent Mexico first led to the recognition of a strong ENSO signal in many of these chronologies. Combination of these data with coral, ice-core, and tree-ring data (including a teak chronology from Indonesia) allowed the reconstruction of

the Southern Oscillation Index between 1707 and 1977 (Stahle et al., 1998). A subsequent tree-ring-based reconstruction of the Niño3 Index, calibrated on sea-surface temperatures, extends back to 1408 (D'Arrigo et al., 2005) and long precipitation-sensitive chronologies from *Austrocedrus* in Chile and Argentina allow the reconstruction of ENSO patterns back over 1500 years in this region (J.A. Boninsegna, 2003, Personal communication). Chronologies from *Polylepis tarapacana* (queñoa) growing at over 4500 m on the Bolivian Altiplano also show a strong correlation with ENSO (Christie et al., 2009; Villalba et al., 2011). Similar studies have reconstructed the Pacific Decadal Oscillation (PDO, Gedalof et al., 2002), North Atlantic Oscillation (NAO; Cook et al., 2002a), and other climate indices from tree-ring data. These large-scale investigations have also

been important in the exploration of teleconnection patterns over time. For example, [St. George et al. \(2010\)](#) have been able to demonstrate the relationships between drought on the Canadian Prairies and several circulatory patterns (ENSO, PDO, AMO, etc.). At a larger scale, [Villalba et al. \(2001, 2011\)](#) demonstrate that the phase relations between tree-ring series from Patagonia and Coastal Alaska show similar patterns at different frequencies over the last 300 years.

Climate-Related Reconstructions

As available databases and investigations diversify, dendroclimatological studies are expanding into several related fields. Temperature-sensitive chronologies have been used to reconstruct sea-surface temperatures (e.g., [D'Arrigo et al., 2005, 2006c](#)). An obvious extension of work on moisture-sensitive sites has been the reconstruction of streamflow. In an early study, [Stockton \(1975\)](#) used 17 chronologies in the Colorado River basin to develop a long streamflow reconstruction which demonstrated that the 1564–1961 mean flow was approximately $2.5 \times 10^9 \text{ m}^3$ less than the 1896–1960 mean and considerably less than the $22 \times 10^9 \text{ m}^3$ base period on which allocation of water rights was based in the 1922 Colorado Compact between the United States and Mexico. In a warming world, more attention is being paid to water supply and streamflow reconstructions and these types of calculations will become increasingly important in watershed planning (e.g., [Meko and Woodhouse, 2005, 2011](#)). [Watson and Luckman \(2004\)](#) used both temperature and precipitation-sensitive tree-ring series to reconstruct the mass balance of Peyto Glacier in Canada over the last 322 years ([Figure 8](#)). Such studies are important in determining the relative roles of precipitation and temperature variability in the past and future behavior of these glaciers in response to climate change. In several mountain areas, summer streamflows are mainly fed by runoff from winter snowpack, and [Pederson et al. \(2011\)](#) have used snowpack-sensitive high-elevation chronologies and lower elevation moisture-sensitive sites to reconstruct snowpack for several large drainage basins in the western Americas.

Tree-ring data have been extensively used to reconstruct 'event' chronologies that show the temporal and spatial

distribution of significant geomorphic or ecological events such as fire, insect outbreaks, major floods, etc. The availability of regional or proximal long temperature and precipitation reconstructions allows examination of the potential climatic controls of such events. Dendrochronology has been widely used to reconstruct forest fire history for individual sites, but studies combining networks of such reconstructions with proxy climate records allow investigation of the climatic controls of these events at interannual, decadal, and centennial timescales ([Figure 9](#)). Synchronous landscape responses to climatic events at continental scales may result in significant ecological changes, which have been characterized as 'ecologically-effective climate change' in the western United States (see [Swetnam and Brown, 2011](#)).

Investigations in the Tropics

One of major gaps in dendroclimatic studies concerns the tropics where few trees have annual rings. In these areas, annual ring development is mainly found in regions with marked seasonality in precipitation ([Worbes, 2002](#)). Recent work has extended chronologies into the subtropics at high elevation sites in the Americas ([Villalba et al., 2011](#)). Precipitation-sensitive chronologies up to 600 years long have been developed from *Polylepis tarapacana* on the Bolivian Altiplano between 18° and 22°S ([Argollo et al., 2004; Christie et al., 2009](#)) and chronologies have been developed from newly investigated tropical and subtropical species east of the Andes in Bolivia and Argentina ([Ferrero and Villalba, 2009; López and Villalba, 2011](#)). Recently, there have been major new collections in SE Asia which are beginning to yield excellent results ([Buckley et al., 2007; D'Arrigo et al., 2006b,c](#)) using teak (*Tectona grandis*) and *Fokienia hodginsii* (locally known as Po Mu) in Vietnam and Cambodia ([Buckley et al., 2010; Sano et al., 2009](#)). Long chronologies have also been developed from the tropics and subtropics in Mexico using both Douglas fir and Montezuma bald cypress (*Taxodium mucronatum*) ([Stahle et al., 2011](#)). There is also promise that isotope dendroclimatology can yield proxy

Figure 8 Reconstructed glacier mass balance for Peyto Glacier, Alberta, Canada, based on separate reconstructions of winter and summer balances using precipitation- and temperature-sensitive tree-ring chronologies. Reproduced from Watson E and Luckman BH (2004) Tree-ring estimates of Mass Balance at Peyto Glacier for the last three centuries. *Quaternary Research* 62: 9–18.

Figure 9 Relationship between regional fires in the southwestern United States and potential climate drivers. *Upper diagram*: tree-ring-reconstructed July–August PDSI (solid line, from Cook et al., 2004) with the largest and smallest regional fire years from a 120-site fire scar network. *Lower diagram*: The same set of fire years plotted with tree-ring-reconstructed Niño-3 index of sea surface temperatures (Cook, 2000) (Tom Swetnam, personal communication, after Swetnam and Brown, 2011, Fig. 3).

climate records from species that lack annual rings (Evans and Schrag, 2004; Gagen et al., 2011).

Changing Signals

Dendroclimatic reconstructions, like many other paleoclimatic techniques, are based on uniformitarian assumptions. However, several authors have noted a decline in the temperature-related signal in both ring width (e.g., Jacoby and D'Arrigo, 1995), and MXD series from high-latitude Northern Hemisphere sites (Briffa et al., 2004) and other studies report changes in signal relating to atmospheric loading effects (e.g., Wilson and Elling, 2004). A variety of causes have been suggested, including increased moisture sensitivity once summer temperatures pass a critical threshold (D'Arrigo et al., 2004), possible ozone-related effects (Briffa et al., 2004), or even chronology development techniques (Wilmking et al., 2005). Although not universal (e.g., Wilson et al., 2007), these effects need careful scrutiny and further study to resolve this critical issue which potentially challenges the validity of

the fundamental uniformitarian assumptions of dendroclimate reconstructions. The potential causes of divergence have been reviewed most recently by D'Arrigo et al. (2008), and Visser et al. (2010) provide a possible technique for identifying these problems. However, it is important to remember that the establishment of 'divergence' requires the demonstration of a change in signal rather than the absence of a temperature signal in the tree-ring record examined.

Concluding Remarks

Dendroclimatological studies are providing new, annually resolved, and precisely dated proxy climate records for large areas of the Earth's land surface and parts of the adjacent oceans. These allow the reconstruction of climate history, trends, and patterns at an expanding range of temporal and spatial scales. The increasing availability of long chronologies from major continental areas can address climate variability at decadal to millennial timescales while retaining annual resolution. The increasing density and distribution of chronologies

provide networks that examine the spatial variability and teleconnection patterns associated with major modes of global climate variability such as ENSO, PDO, NAO, and the Asian Monsoon. As these networks of annually resolved data are minimally at least double or triple the length of instrumental records (in many remote areas they may be the only records), they can be used to establish whether these patterns are time-stable or how they have responded to past changes in forcing. In conjunction with other proxy climate data, they provide the best records to benchmark and understand the natural modes of climate variability at decade-to-century scales over much of the Earth's surface. The growing availability of long individual or gridded temperature and precipitation reconstructions also allows exploration of the relationships of between critical episodes in human history and large-scale climate events. [Stahle and Dean \(2011\)](#) provide many examples of the human impact of drought in North America over the last millennium. More recently, [Büntgen et al. \(2011\)](#) have examined the relationships between significant events in European History and the temperature and precipitation signals derived from European oak and pine chronologies of the last 2500 years. PDSI and drought reconstructions have also shed light on possible causes for the collapse of the Khmer ([Buckley et al., 2010](#)), Mayan, Toltec, and Aztec civilizations ([Stahle et al., 2011](#)). Thus, whilst dendroclimatology plays a central role in documenting climate variability, it can also be used to understand the important role these changes play in geomorphic, ecological, and human histories of the last millennium.

Acknowledgments

I would like to thank J.A. Boninsegna, K.R. Briffa, D.W. Stahle, M.D. Terrell, R.J.S. Wilson, and Emma Watson for help in preparing this paper.

Diatom Introduction

The Biology of Diatoms

The word 'diatom' derives from the Greek, meaning cut in two. Diatoms (Bacillariophyta) are unicellular, eukaryotic (complex cells where the genetic material is found in membrane-bound nuclei) microscopic organisms belonging to the Kingdom Protista. They are pigmented and usually appear golden brown in color; they are photosynthetic although a few species are facultative or obligate heterotrophs (i.e., feeding on other organisms). The characteristic feature of the diatom is its cell wall, which is almost always heavily impregnated with silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$).

Globally, diatoms are very important as members of the planktonic food chain for large parts of the planet. They play a key role in the global carbon cycle. Diatom photosynthesis in the ocean yields as much as 40% of the organic carbon produced each year in the sea, and their role in global carbon cycling is predicted to be comparable to that of all the terrestrial rain forests combined, fixing about 20% of the carbon each year. Over geological time, diatoms may have influenced global climate by changing the flux of atmospheric carbon dioxide into the oceans.

Diatoms reflect a fundamentally different evolutionary history from the higher plants that dominate photosynthesis on land. They share biogeochemical features of both plants and animals. The marine centric diatom *Thalassiosira pseudonana* was chosen as the first eukaryotic marine phytoplankton species for whole-genome sequencing. The genome is relatively small at 34 mega base pairs (Armbrust et al., 2004). There is a well-documented fossil record of the diatoms from the middle Cretaceous with some records from the early Jurassic gap. There are a large number of Eocene/Miocene diatom fossil deposits situated around the world, which are mined commercially as diatomite; Flower (this volume) deals with the Quaternary diatomites. Further details of diatom biology are given in Round et al. (1990) and van den Hoek et al. (1995).

The Structure of the Diatom Frustule

The silica cell wall of diatoms is box-like in structure, always made of two halves, called valves. The upper one (the epivalve or epitheca) is slightly larger than the lower valve (hypovalve or hypotheca; Figure 1) and they are linked together with girdle bands. The valves are intricately sculptured and when organic material is removed by cleaning, the frustule splits into two. Most Quaternary applications are based on the observation of these fragments.

Diatoms are the most species-rich group of algae and there may be as many as 200 000 species. Although traditionally most diatom systematic studies have been based on valve features observed under the light microscope, recent developments through electron microscopy, the examination of living material, and molecular techniques have resulted in many nomenclatural changes, and consequently the taxonomy can be confusing.

Round et al. (1990) propose three classes of diatom: the Centrics, (Coscinodiscophyceae), pennates without raphe (Fragilariophyceae), and pennates with a raphe (Bacillariophyceae). These are shown in schematic form in Figure 1.

Features of the Valve

Most diatoms contain areolae (Figure 1) that appear to be simple perforations through the cell wall, although internally they are occluded by a finely perforated velum. These areolae are usually arranged in rows of striae. The characteristics of these are used extensively for identification purposes, for example, the spacing between striae (i.e., the striae density) and the pitch of the striae. The raphe is one of the most important features used to separate suborders or classes. It is an elongated fissure or pair of fissures through the valve wall. The naviculoid raphe (Figure 1(c)) runs along the central axis of the valve and is divided in two, separated by the central nodule.

Diatom shape varies, usually being round or boat shaped, but is sometimes triangular, square, or elliptical. The cell wall is highly patterned with an array of pores, ribs, spines, and processes that can be used for identification purposes. Their spectacular forms have been appreciated since the invention of the microscope and have formed the subjects of many wonderful illustrations (Figure 2).

Cells are solitary (Figure 3) or united into colonies (Figure 4) which may be linked by siliceous structures such as spines or bipolar elevations (e.g., *Eucampia*) or by mucilage (e.g., in tubes in genera such as *Nitzschia*).

Motility is limited to those pennate species that have a raphe, and occurs through secretion of mucopolysaccharide filaments which become attached to the solid substrate enabling the diatom to 'ooze' along a surface. A unique way of moving is displayed by the pennate diatom *Bacillaria paradoxa* (= *Bacillaria paxillifera*); this species forms small colonies in which individual cells slide back and forth over one another so the shape of the colony can change from a square to a linear form and back again.

The uptake and deposition of silica is one of the characteristic features of diatoms. This leads to rigidity of the cell walls and preservation as fossils. The characteristics of the silica cell wall are also used in their taxonomy. Leng and Barker (this volume) give a more detailed account of the uptake of silica and Tyler (this volume) discusses the use of isotopes of silica in the Quaternary.

Lifecycles and Life Form

Diatoms are unusual in that vegetative cell division usually results in the size of the population becoming successively smaller and smaller. This is because the daughter cell is formed within the confines of the rigid parent cell. In some species, this

Figure 1 A schematic diagram illustrating the three main classes of diatom: (a) a typical centric form Coccinodiscophyceae, showing radial symmetry (e.g., *Stephanodiscus*) and pattern of areolae radiating from the center of the valve; (b) a typical pennate diatom without a raphe Fragilariophyceae (e.g., *Staurosira*) with areolae are usually arranged in rows or striae, in this case striae are parallel; (c) a typical pennate diatom with a raphe Bacillariophyceae (e.g., *Pinnularia*) with a naviculoid raphe running along the central axis of the valve which is divided into two separated by the central area; (c') a pennate diatom Bacillariophyceae (e.g., *Nitzschia*) with an eccentric raphe. Adapted from Round FE, Crawford RM, and Mann DG (1990) *The Diatoms: Biology and Morphology of the Genera*. Cambridge: Cambridge University Press, with kind permission from Cambridge University Press.

can, over many generations, result in a considerable reduction in size which can lead to problems in their identification and classification as the full-size ranges of most species are unknown. In centric species, the main features of the valve are unaltered, but in pennate species, the width often decreases less than the length (see Figure 5). Although size reduction is often ignored by Quaternary scientists, there are potential applications (e.g., Cortese and Gersonde, 2007; Simola, this volume).

Size is restored after sexual reproduction, and diatoms show a range of different types of sex. The Centrics are oogamous (i.e., they have eggs and flagellate sperm) while the pennates have morphologically similar gametes, which are nonflagellate. In all cases, copulation takes place between the two haploid gametes producing a diploid zygote, the auxospore. The auxospore then swells and when it has enlarged fully, a new vegetative cell is formed within it. The complete lifecycle has rarely been observed in natural populations, but in some species at least, it seems to take a considerable time, for example, at least 6 years for *Nitzschia sigmaidea*, and 7–8 years (based on observations of specimens from varved sediments) for *Tabelaria fenestrata* (Mann, 1988).

Diatom resting spores are dormant cells that are produced as a response to unfavorable conditions, mainly by centric diatoms. The spores contain stored energy in the form of photosynthetic products and have tough, thickened cell walls. They sink to the bottom of the water column and can return

to normal cell functioning if favorable conditions return. Some are morphologically distinct (e.g., *Chaetoceros* spp.) while others are not (e.g., *Aulocoseira subarctica*). In *Chaetoceros*, resting spore formation is associated with nutrient exhaustion in the water column, after mass multiplication of vegetative cells following an upwelling event. *Chaetoceros* resting spores, therefore, provide a record of paleobloom events in the ocean (Pike and Stickley, this volume). In continental saline waters, the very heavily silicified resting spores are often all that remain of a diatom assemblage after dissolution.

Diatom Habitats

Diatoms are distributed in all waters except the hottest and most hypersaline and most samples obtained from aquatic habitats contain some diatom cells.

Marine Habitats

Diatoms occur in all oceans from the poles to the tropics, but are most abundant in polar-to-temperate regions. These are mostly planktonic species. True planktonic species spend all of their lifecycle in open water, depending primarily on water currents for their buoyancy. Large blooms sometimes descend the water column *en masse* as mats (see Pike and Stickley, this

Figure 2 The variety of marine diatoms as illustrated by E Haeckel (1904; *Artforms in Nature*. Dover Press Pictorial Archive Series, Copyright-free).

volume). As well as growing as plankton in open waters, they grow attached to various substrates in the coastal zone, for example, as epiphytes on seaweeds or as epilithon on rocks. Diatoms also form biofilms on the surface of intertidal mudflats; the motile forms show a remarkable tidal rhythm. On mudflats, diatoms influence sediment stability by increasing sediment cohesion through the excretion of extracellular polysaccharides. By reducing erosive stress, diatoms promote the silt content of the sediment, and high densities of diatoms significantly reduce the frequency and magnitude of erosion events in some coastal areas.

In the coastal zone, Quaternary scientists have used diatom salinity preferences and life forms for environmental reconstruction (Cooper et al., 2010; Snoeijs and Weckström, 2010; Trobajo and Sullivan, 2010) and used diatoms to determine paleoceanographic conditions (Koizumi, this volume). Other applications include sea-level reconstruction, studies of basin isolation, paleotidal reconstructions, studies of salt marsh development, inference of tsunami events, and biological indicators of pollution (e.g., eutrophication, radionuclide contamination) which are detailed extensively in

Smol and Stoermer (2010). Zong and Horton (1999) modeled the relationship between diatom assemblages and tidal levels and developed a diatom-based tidal-level transfer function which was applied successfully to estimate paleotidal levels from fossil diatom data recorded in late Holocene coastal sequences.

A unique habitat is formed by the seasonal expansion and contraction of sea ice at the poles. Diatoms can grow attached to the underside of the ice as well as interstitially and attached to ice platelets. These different communities can be distinguished and have been used to trace the development of sea ice in the Quaternary (Stickley et al., this volume; Koç et al., this volume). Sea ice diatoms can leave biomarkers in marine sediments and these have been used as a proxy for past sea ice presence (see Belt et al., this volume).

Freshwater Habitats

Planktonic diatoms

As in the oceans, planktonic diatoms are common in open water. In lakes, however, many forms are not truly planktonic

Figure 3 A scanning electron micrograph of *Cyclostephanos tholiformis*, a typical centric diatom. Photograph by C. Sayer.

as they spend some of their lifecycle resting on the sediment (meroplanktonic; e.g., some *Aulocoseira* spp.). However, planktonic species from both lakes and oceans are subject to two special influences: the availability of silicate and the tendency of diatoms to sink as they are as dense as or denser than water. However, the photic zone is often turbulent due to winds, currents, and convection; therefore, many diatoms exhibit features such as a long cylindrical shape or long chains which slow their sinking velocity. In the northern temperate lakes, there is a well-established pattern of seasonal succession in the plankton with a spring bloom, a subsequent decline (as silica is depleted), and a second peak in autumn. The species are often distinct, due mainly to nutrient differences between spring and autumn, and therefore this information has been used to interpret climate and weather patterns. In Elk Lake, Bradbury et al. (2002) interpreted changes in the ratio of *Stephanodiscus*

Figure 5 Diatom vegetative reproduction. minutulus and *Fragilaria crotonensis* as indicative of shifts between long, dry springs and warm, stormy summers. In addition, wavelet analysis suggested strong periodic correlations between individual diatom species and various sunspot cycles such as the 11-year Schwabe cycle (see also Mackay et al., 2003).

In both marine and freshwater habitats, the distinction between plankton and benthos is not absolute, as well as the meroplanktonic forms; species which have their true habitat in the benthos can often be found resuspended in the water column (tychoplanktonic).

Benthic diatoms

Benthic diatoms are often very diverse and can live either free on or in the sediments, or attached to the substratum, for example, rocks (epilithon), sand grains (epipsammon), and plants (epiphyton). Diatoms living on soft sediments (epipelion) where the chances of burial are high are often motile species that are able to migrate up and down in the sediment matrix. Attached communities can be adnate (i.e., closely attached to the substrate; e.g., *Cocconeis*) or attached by mucilaginous stalks or pads (e.g., *Gomphonema*). Often diatoms can group themselves into three-dimensional (3D) communities forming complex microscopic 'forests' (Figure 6). Diatoms can also form part of the diverse 3D microbial communities of filamentous algal mats which form in streams and lakes, in some cases forming perennial layers up to 30-cm thick.

Although diatoms rarely have very discrete habitats (there are often overlaps between species from different communities), habitat information is still useful for Quaternary scientists. For example, Sayer (2001) suggested that a recent increase in *Cocconeis placentula*, a very common epiphyte in Groby Pool,

Figure 6 A colony of *Tabellaria quadriseptata* frozen *in situ* and examined by scanning electron microscopy. Photograph by R. Flower.

was due to an increase in macrophytes in the lake over the last 50 years caused by increasing nutrient enrichment. In this study, a shift from benthic *Fragilaria* communities to planktonic communities dominated by *Stephanodiscus parvus*, *Cyclotella tholiformis* (Figure 3) and *Cyclotella dubius* was also seen as a consequence of nutrient enrichment. Although the ratio of benthic to planktonic species can give useful information about the changing trophic state of some lakes, there has been a shift to the use of quantitative statistical methods (see Section ‘Diatoms and Quantitative Inferences of Past Water Quality Using Transfer Functions’) for reconstructing lake eutrophication.

Aerophilic diatoms

Diatoms can also grow as subaerial forms (aerophilic) on damp rock faces, terrestrial soils, or even on the leaves of plants growing in damp environments. These include species such as *Hantzschia amphioxys*, *Diadesmis* spp., some *Pinnularia* spp., and large chain-forming *Orthoseira* spp.; some of these are obligate aerophiles (Johansen, 2010). When these are preserved in sediments, they can provide useful information for environmental scientists, indicating drying out of a water body, for example.

River diatoms

In rivers, diatoms can grow attached to substrates, and in large rivers they can form a planktonic community. Some pennate species such as *Meridion circulare* (Figure 4) and *Hannaea arcus* are characteristic of running waters while a characteristic centric species of running water is *Melosira varians*. Stream velocity is an important determinant of both species composition and the physical structure of communities. Quaternary applications in lotic ecosystems are clearly limited, owing to the lack of continually accumulating sediments. However, undisturbed sediments can be found in reservoirs or deltas and in paleochannels and floodplain lakes in lowland river systems. The floodplains of relatively large, lowland rivers often have old channel systems (paleochannels) and associated oxbow cutoff lakes (or billabongs). Such systems are low energy and thus provide suitable sedimentary environments for paleoecological study using diatoms (Reavie and Edlund, 2010). Thoms

et al. (1999) determined the impact of agriculture and river regulation on water quality in billabongs of southeastern Australia using the fossil diatom record. Reavie and Smol (1997) developed reliable transfer functions for reconstructing past habitat conditions based on diatom habitat preferences (rock, *Cladophora*, macrophytes) in the St. Lawrence River, Canada. The models were applied to a fluvial sediment sequence and showed a marked increase in macrophyte-associated diatom taxa which the authors attributed to accelerated nutrient inputs. Ludlam et al. (1996) used a simple indicator for the relative contribution of running-water communities in an arctic lake. The Lotic Index showed a clear positive relationship to sedimentation rate as recorded in the varves, and therefore seem to be a good indicator of stream flow.

Biogeography and Endemism

There has often been an emphasis on the cosmopolitan nature of diatoms. While some species have a global distribution, for example, *Achnanthes minutissimum*, others may not be as widespread as has been suggested. This is due to a number of factors: for example, the uncritical use of floras from other regions and taxonomic clumping of closely related taxa. Certainly it seems that the numbers of diatom species have been underestimated, and when careful taxonomic work is done, several species that cannot be attributed to published species are almost always identified for the first time. Endemism describes diatoms that are restricted to a particular location. The best-known examples of endemic diatom floras are island floras and long-lived or ancient freshwater lake systems such as those found in Lake Baikal, Lake Ochrid (Macedonia), or the African Rift Lakes (Mackay et al., 2010). The endemic flora of Lake Baikal and its application to paleoclimate reconstruction is discussed by Mackay (this volume).

Collecting and Studying Live Diatoms

Live diatom material can be collected from different habitats using a variety of means; attached diatoms can simply be scraped off rocks or plants using a brush, a known area of substrate can be used if density data are required. A lens tissue can be used to collect motile forms. Planktonic forms can be sampled with a bottle or plankton net. Diatoms can also be frozen *in situ* to preserve their 3D architecture (Figure 6). Normally, though, samples are preserved with a few drops of Lugol's iodine to retain the form and position of the chloroplasts. Even though most taxonomy is based on the cleaned frustule, it is possible to identify living diatoms using cell and colony features (Cox, 1996). Although often ignored by Quaternary scientists the identification of live versus dead cells can be informative as to whether modern diatoms collected from a particular habitat are actually living there or whether they have been transported there after death. Diatomists working with lake sediments need to sample both living and fossil communities to develop transfer functions and to understand the relationship between source communities and fossil assemblages. Further details of field sampling and coring are given in Battarbee et al. (2001).

Cleaning and Sample Preparation

In most Quaternary applications fossil diatoms need to be separated from the sedimentary matrix. The precise steps depend on the nature of the material and care needs to be taken not to lose or damage valves. For example, delicate diatoms can easily be broken by rapid centrifugation. Figure 7 illustrates the

basic steps needed, but often the removal of organic matter by oxidation with either hydrogen peroxide, strong acids, or by incineration is all that is required. Once cleaned material is obtained, permanent slides can be made by mounting in a suitable medium with a high refractive index (>1.7) such as Naphrax (refractive index 1.73). Diatom concentrations can be calculated by adding a known quantity of markers such as

Figure 7 Flow chart for sample and slide preparation. Reproduced from Battarbee RW, Jones VJ, Flower RJ, et al. (2001) Diatoms. In: Smol JP, Birks HJB, and Last WM (eds.) *Tracking Environmental Change Using Lake Sediments. Terrestrial, Algal and Siliceous Indicators*, vol. 3, pp. 155–202. Dordrecht: Kluwer Academic, with kind permission from Springer Science and Business Media.

divinylbenzene microspheres which are commercially available in the 5–10 μm size range. For further details on preparation techniques, see [Battarbee et al. \(2001\)](#).

Identification

Most diatom assemblages are diverse and some expertise is needed for identification. Identification to the generic level is relatively straightforward although it requires some familiarity with terminology. Recent keys to genera include [Barber and Haworth \(1981\)](#), [Kelly \(2000\)](#), and [Tomas \(1996\)](#). Once familiar with the genera, more specialized floras are needed (e.g., [Krammer and Lange-Bertalot, 1986](#)); ideally these should be generated from the same geographic region as the diatom sample. In addition, there are more specialized floras for specific ecosystems or specific genera which are available as books, CD-ROMs, and on the Internet. Databases such as the European Diatom Database (<http://craticula.ncl.ac.uk/Eddi/jsp>) combine information on the distribution of diatoms in surface sediment datasets, including images, with the ability to perform online reconstructions.

Enumerating Diatoms

Most routine counts are based on the light microscope using oil immersion objectives and magnifications of 750–1500 $\times$. Bright field, phase contrast, or differential interference contrast illumination can be used, and an eyepiece graticule is useful for measuring. Digital cameras with image capture software are increasingly being used to manipulate and store images.

Diatoms species counts are commonly expressed as a percentage of a total diatom sum or as a concentration value. Commonly the sum comprises all taxa but occasionally it is useful to exclude some groups, for example, when these can be identified as clear contaminants from reworked material. Appropriate counting strategies need to be developed for individual sequences and to ensure that a representative proportion of the coverslip is examined and that broken fragments of valves are identified and enumerated. Concentration data can be expressed as the number of valves per gram of sediment, or more usefully they can be used to produce a diatom accumulation rate in valves per gram per year. As diatoms vary considerably in size, this statistic may not be particularly meaningful unless it is converted to biovolume.

Preservation and Taphonomy

The preservation of diatoms in sediments ranges from excellent in diatomites (see [Flower, this volume](#)) to poor in some saline lakes ([Fritz, this volume](#)) and in extreme cases no diatoms are preserved in the sediment. Factors affecting preservation include salinity, temperature, alkalinity, and sediment accumulation rate as well as the silica content of the cell and the concentration gradient of dissolved silica between the sediment and overlying water. Differential dissolution can occur leading to bias in the composition of the assemblage to more robust forms ([Ryves et al., 2003](#)). A key question is whether diatoms preserved in the sediment actually reflect the communities from which they are derived. Taphonomic processes

include removal from the outflow of lakes, resuspension and reworking of older sediments, losses through grazing, bioturbation in the sediment, and dissolution. Some studies show a good agreement between the composition of live communities and the sediment record (e.g., [Cameron, 1995](#)) while some studies show considerable differences between diatoms found in the water column and the sediment record. For example, in Lake Baikal the majority of diatoms dissolve before reaching the sediment surface (see [Mackay, this volume](#)).

Diatoms as Paleoenvironmental Indicators

Besides the types of habitats available, there are other controls on the composition of the diatom flora. Physical controls include temperature, turbulence, and light. Chemical controls include factors such as pH, nutrients, and salinity. Biological controls such as grazing and parasitism are also important.

The ubiquitous nature of diatoms is one reason why diatoms are widely used as biological indicators in Quaternary paleoecology ([Smol and Stoermer, 2010](#)) and they have been used to provide information specifically for archaeologists (see [Cameron, this volume](#)) as well as a wide range of past environmental and ecological changes, such as climatic and lake-level changes, water pollution, eutrophication, and acidification.

Fossil diatoms have been used as indicators of environmental change on a range of time scales from decadal to millennial. Many studies have focused on Late Glacial and Holocene sequences, but long diatom records encompassing several glacial–interglacial cycles are available from marine and freshwater sequences (e.g., see [Koc, this volume](#); [Mackay, this volume](#)). In recent decades, progress has been made in our methods of interpreting diatom stratigraphical data through powerful numerical techniques that allow accurate quantitative reconstructions of environmental change to be made ([Birks, 2010](#)).

Diatoms are excellent paleoindicators in Quaternary studies ([Korhola, 2007](#); [Smol and Stoermer, 2010](#)), because:

- They are common in aquatic systems.
- They are diverse, and communities are usually represented by many taxa which increase the ecological information gained and the confidence of environmental inferences.
- Diatoms show a broad range of tolerance along environmental and ecological gradients, with individual species having specific ecological and water quality requirements that are usually quantifiable. [Figure 8](#) shows how different species respond along a pH gradient.
- They have short generation times so can respond rapidly to environmental change.
- Their siliceous frustules are resistant to degradation and they are often well preserved in different sedimentary environments.
- The taxonomy of diatoms is relatively well known and allows identification of fossil diatom assemblages to the species or even subspecies level.

Diatoms and Quantitative Inferences of Past Water Quality Using Transfer Functions

Diatoms have been used to quantitatively infer past conditions with a range of techniques. The early applications were

Figure 8 Fitted Gaussian response curves for four diatom species along a pH gradient. Data are from the SWAP dataset of 167 lakes from England, Wales, Scotland, Norway, and Sweden (Stevenson et al., 1991), with kind permission from Cambridge University Press.

developed for pH inference and were based on species categories and indices, later multiple linear regression models were developed to estimate pH according to the proportions of the established pH-preference groups (Battarbee et al., 2010). More recently, paleoecologists have used the ecological optima and tolerances of diatom assemblages to construct transfer functions that allow environmental conditions to be inferred from fossil assemblage data (Birks, 2010). Transfer functions have been used for a range of inferences and Quaternary applications including reconstructing nutrients (Bennion et al., 2010), salinity (Fritz, this volume), conductivity (Mackay, this volume) and sea-surface temperature (Koç, this volume).

Transfer functions are used to describe the relationship between diatom assemblages and their environment and then this relationship is applied to past assemblages to quantitatively infer past conditions. The basic approach is illustrated as a hypothetical example in Figure 9 (this is Figure 6 from Korhola, 2007) and involves two steps: (1) the regression step in which the responses of taxa to the contemporary environment are modeled and (2) a calibration step in which the environmental variable of interest is predicted from the fossil compositional data. Transfer functions are established using modern diatom assemblages and measured environmental variables from a calibration dataset (also called a training set; Figure 9(a)) which are created by sampling a large (between 30

and 200) number of sites (e.g., lakes, wetlands, estuaries, and marine environments) along the environmental gradient of interest (e.g., pH, nutrient, and water temperature) for water chemistry and surface sediments (the uppermost sediment representing recent sediment accumulation; Figure 9(b)). The transfer function approach is based on the implicit assumption that the modern training sets cover the range of environmental conditions likely to be represented by the fossil assemblages. Hence, calibration datasets should ideally span all biologically relevant environmental gradients.

There are now many numerical techniques for deriving transfer functions. Simple two-way weighted average regression and calibration, weighted-averaging partial least squares (WA-PLS) regression and calibration, Gaussian logit regression (GLR), and maximum likelihood (ML) calibration are relatively statistically robust and computationally economical and have been widely adopted (Birks, 2010). Ideally the reliability of transfer functions can be assessed by comparison with measured historical data (e.g., Fritz, 1990) but such datasets are rare. Alternatively, diatom-based reconstructions can be compared with independent paleoenvironmental data. Without either historical validation, or independent data, evaluation needs to be made indirectly using numerical criteria which include analog measures, 'goodness-of-fit' statistics, and sample-specific errors (Birks, 2010).

Figure 9 Simplified illustration of the typical steps involved in developing and assessing the predictive ability of a diatom-based calibration model and its application to fossil diatom data including: (a) selection of a modern training dataset; (b) estimation of taxon responses based on their distribution in the training set (regression); (c) generation of a transfer function on the basis of the training set (calibration); (d) selection of an independent test set to assess the transfer function (calibration); (e) use of computer resampling techniques, such as jackknifing or bootstrapping, to assess the transfer function (calibration); and (f) reconstruction of parameter value from fossil diatom assemblages and estimation of sample-specific prediction errors by bootstrapping. Introduction

Diatom silica is a form of biogenic opal ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$, [Figure 1](#)) that contains oxygen isotopes and can be used in lacustrine and marine paleoenvironmental studies. The oxygen isotope ratio ($^{18}\text{O}/^{16}\text{O}$) of diatom silica is expressed on the delta scale (δ) in terms of per mille (or per mil) (‰):

$$\delta = [(R_{\text{sample}}/R_{\text{reference}}) - 1] \times 1000\text{‰} \quad [1]$$

where R is $^{18}\text{O}/^{16}\text{O}$, and 'reference' means the appropriate universally accepted reference material. The ' δ ' for each element takes its name from the heavy isotope, thus $\delta^{18}\text{O}$. For diatom oxygen, the reference is Vienna Standard Mean Ocean Water (VSMOW), a specially prepared distilled seawater. There is no universally accepted standard material for oxygen isotopes from diatom silica ($\delta^{18}\text{O}_{\text{diatom}}$), although most laboratories analyze it alongside the NBS28 (quartz) and their own standard diatomites. VSMOW and NBS28 are held and distributed by the International Atomic Energy Agency (IAEA) in Vienna.

Diatoms form a shell or frustule, following a seasonal pattern defined by the variability of climate, nutrient supply, mixing regimes, and at high latitudes the period of ice cover. The isotope signature acquired by diatoms will, therefore, be skewed toward their major growing season, which will be specific to the lake or oceanic region under consideration.

Analytical Considerations

Analytical techniques for measuring $\delta^{18}\text{O}_{\text{diatom}}$ will generally liberate oxygen from all the components in the sediment, for example, silt, clay, tephra, carbonates, other siliceous organisms and organic matter. Since the presence of contaminants

will distort the $\delta^{18}\text{O}_{\text{diatom}}$ signal, it is important that the sample is almost entirely composed of diatom frustules. Similarly, only pristine samples should be analyzed due to the risk of isotopic fractionation occurring during diagenesis and dissolution, leading to an increase in $\delta^{18}\text{O}_{\text{diatom}}$ ([Moschen et al., 2005](#)). Published methods of removing contamination involve various stages of chemical attack (including HCl, H_2O_2 , HNO_3), sieving, differential settling ([Figure 2\(a\)](#) and [2\(b\)](#)) and the use of heavy liquids and gravitational split-flow thin (SPLITT) fractionation ([Figure 3](#)).

Disequilibrium effects (commonly known as 'vital' effects in the case of biogenic carbonates) include a variety of rate effects and microenvironment-induced changes that cause the mineral to have an isotope composition that is different from that predicted purely by thermodynamics. A number of studies on both marine and lacustrine taxa have failed to find any evidence for such a process in $\delta^{18}\text{O}_{\text{diatom}}$ outside of analytical error (e.g., [Brandriss et al., 1998](#); [Juillet-Leclerc and Labeyrie, 1987](#); [Moschen et al., 2005](#); [Sancetta et al., 1985](#); [Schiff et al., 2009](#); [Schmidt et al., 2001](#); [Shemesh et al., 1995](#)). An exception is a stratigraphic record from the North Pacific Ocean which displays significant variations between different size fractions, each containing different taxa ([Swann et al., 2007, 2008](#)). Further work is required to fully understand the processes behind these changes, demanding the need for caution when analyzing $\delta^{18}\text{O}_{\text{diatom}}$ in bulk samples containing numerous taxa. Attempts are ongoing to develop a means of routinely extracting individual species for isotope analysis.

Analytical Methods

The chemical structure of a diatom can be described by defining Q_n where Q represents a silicon atom surrounded by n

Figure 1 Diatom silica is a form of biogenic opal and has the chemical formula $\text{SiO}_2 \cdot n\text{H}_2\text{O}$. Here the structure of biogenic silica is shown in a 2-nm particle. The core of the particle is the only part predominantly made up of Q_4 , while subsequent layers contain a mixture of Q_n species. Q represents a silicon atom surrounded by four oxygen atoms while suffix n gives the number of surrounding oxygen atoms (out of 4) that are bonded to another silicon atom.

oxygen atoms. Frustules contain a Q_4 , tetrahedrally bonded silica (Si—O—Si) layer, surrounded by more hydrous, Q_3 , material (Si—OH). The exact distribution of oxygen in the frustule, however, is more complex than simple layering and is related to the mode of frustule formation and its differential porosity. Oxygen in the hydrous layer, amounting to ~5–40% of the frustule, is freely exchangeable with any water the diatom silica comes into contact with during sample preparation and must be removed prior to analysis using oxidizing reagents and/or high temperatures.

Breaking the internal Si—O bond requires considerable energy, and four main methods have been developed to obtain the $\delta^{18}\text{O}_{\text{diatom}}$ paleoenvironmental signal stored within the tetrahedrally bonded, Q_4 , layer: controlled isotope exchange (CIE), stepwise fluorination (SWF) techniques, inductive high-temperature carbon reduction (iHTR) and inert gas flow dehydration (iGFD) method. iHTR and iGFD are based on the thermal reduction and dehydration of silica at high temperatures (1100–1550 °C for biogenic silica; Chapligin et al., 2010; Lücke et al., 2005). The other two techniques involve the use of a fluorine-based compound such as F_2 , ClF_3 , or BrF_5 (extremely powerful oxidizing reagents) to liberate the oxygen from the diatom silica. The CIE method uses the fact that the surficial hydrous silica (Si—OH) is reactive under much lower energy conditions than the inner tetrahedrally bound silica, which allows oxygen atoms of known isotope composition to be exchanged with the unstable hydrous material while leaving the skeletal silica intact (Labeyrie and Juillet, 1982). The method exchanges oxygen in Q_3 bond, hydrous silica, with oxygen of a known isotope value, and then through mass balance calculations determines the composition of the non-exchangeable silicate oxygen after fluorination. The SWF method involves reacting the silica with a fluorine compound in a series of steps (Figure 4) and was first described by

Haimson and Knauth (1983). Oxygen from Q_3 bonds are disassociated from the biogenic silica in the first step leaving the structurally bound silica for subsequent reactions (Leng and Sloane, 2008).

Typically, between 1.5 and 6.5 mg of material is required for a single analysis depending on the analytical procedure being followed. Interlaboratory comparisons demonstrate comparable results between each technique (B. Chapligin, personal communication). However, the difficulties of purifying the material and the extraction of formation water oxygen means that the analytical reproducibility of diatom silica oxygen isotope ratios is generally quoted as ~0.2–0.3‰. This is significantly higher than for carbonate $\delta^{18}\text{O}$ which has a precision in the range of $\pm 0.05\text{‰}$ (for pure carbonate minerals) to $\pm 0.1\text{‰}$ (for authigenic carbonates) within sediments.

Diatom Oxygen Systematics

Changes in $\delta^{18}\text{O}_{\text{diatom}}$ can be used to infer changes in either the temperature or the $\delta^{18}\text{O}$ composition of the water in which they grew ($\delta^{18}\text{O}_{\text{water}}$; Figure 5). As outlined in the sections below, the controls on $\delta^{18}\text{O}_{\text{water}}$ will depend on the nature of the site for both marine and lacustrine environments.

Temperature

A number of water column and culture experiments have suggested a $\delta^{18}\text{O}_{\text{diatom}}$ –temperature relationship in lacustrine taxa of $\sim 0.2\text{‰} \text{ } ^\circ\text{C}^{-1}$ (Brandriss et al., 1998; Crespin et al., 2010; Dodd and Sharp, 2009; Moschen et al., 2005). The temperature dependence in marine taxa has not been as rigorously derived with measurements based on bulk rather than species or genera-specific samples. In the first of these studies, Juillet-

Figure 2 (a) Diagram showing the four-stage cleaning method for concentrating diatom for oxygen isotope analysis from lake sediments. SPT, Sodium polytungstate. Reproduced from Morley DW, Leng MJ, Mackay AW, Sloane HJ, Rioual P, and Battarbee RW (2004) Cleaning of lake sediment samples for diatom oxygen isotope analysis. *Journal of Palaeolimnology* 31: 391–401, with kind permission from Springer Science and Business Media. (b) Lake sediment samples from Lake Rutundu, Mount Kenya before and after cleaning, (i) shows the sample after standard diatom preparation using HCl and H_2O_2 and (ii) shows the cleaned sample after a staged cleaning approach. Species diversity has been reduced by the cleaning procedure, leaving the sample dominated by large *Cymbella* and *Epithemia* spp.

Leclerc and Labeyrie (1987) conducted a global calibration using surface-sediment assemblages to produce a calibration between sea surface temperatures (SST) of 1.5 and 24 °C:

$$T(^{\circ}\text{C}) = 17.2 - 2.4(\delta^{18}\text{O}_{\text{diatom}} - \delta^{18}\text{O}_{\text{water}} - 40) - 0.2(\delta^{18}\text{O}_{\text{diatom}} - \delta^{18}\text{O}_{\text{water}} - 40)^2 \quad [2]$$

Although this work was supported by Matheney and Knauth (1989), Shemesh et al. (1992) reported that the calibration significantly overestimates temperature in high-latitude sites. By selecting only the high-latitude data points from Juillet-Leclerc and Labeyrie (1987), Shemesh et al. (1992) suggested that a calibration of $-0.5\text{‰}^{\circ}\text{C}^{-1}$ was more appropriate for such regions. However, most work points to a coefficient of approximately $-0.2\text{‰}^{\circ}\text{C}^{-1}$, although further work is needed in marine systems to establish an accurate $\delta^{18}\text{O}_{\text{diatom}}$ -temperature calibration.

Silica Maturation

When analyzing $\delta^{18}\text{O}_{\text{diatom}}$ from sediments, consideration must be given to the role of silica maturation, often referred to as secondary isotope exchange, in which isotopically light ^{16}O from the $-\text{Si}-\text{OH}$ layer is released with ^{18}O forming isotopically enriched Q_4 bonds (Figure 1) in the $-\text{Si}-\text{O}-\text{Si}$ layer of the frustule (Brandriss et al., 1998; Dodd and Sharp, 2009; Moschen et al., 2005; Schmidt et al., 1997; 2001):

At present, the implications of these changes remain under investigation. On the one hand, silica maturation should erode any surface water $\delta^{18}\text{O}$ signal to produce a more muted record reflecting a combination of both surface and bottom water conditions. However, as outlined below, numerous studies

Figure 3 (a) An alternative approach to heavy liquid separation for cleaning diatom samples is gravitational split-flow thin fractionation (SPLITT) developed by J.C. Giddings at the University of Utah and first applied to the separation of diatoms by [Schleser et al. \(2001\)](#) and [Rings et al. \(2004\)](#). (b) SPLITT works by introducing a sample (A) into a thin channel where it meets a carrier fluid (B, usually water for diatom samples) in a laminar flow. The inlet splitter plane (ISP) and outlet splitter plane (OSP) divide the flow. The velocity of the two flows is controlled to separate the sample into two streams: an upper A sample containing finer, less dense, and more hydrodynamic particles passes through one outlet (C), while the remaining particles are collected through a lower outlet (D). The SPLITT cell is inclined to reduce deposition of sediment onto the splitter plate at low flows.

have demonstrated strong correlations between $\delta^{18}\text{O}_{\text{diatom}}$ and other surface water records with no evidence that silica maturation prevents the use of $\delta^{18}\text{O}_{\text{diatom}}$ to reconstruct surface water conditions ([Leng and Barker, 2006](#); [Leng and Swann, 2010](#)).

Lake reconstructions

Temperature

In the lacustrine environment, the interpretation of the measured oxygen isotope data from diatom silica in terms of paleotemperatures requires an understanding of two temperature effects that have opposing effects on the composition of diatom silica. There is the fractionation between diatom silica and water, described above, which has a gradient of $-0.2\text{‰}\text{°C}^{-1}$. There is also the relationship between precipitation and temperature (the so-called Dansgaard relationship $\delta p/dT$; [Dansgaard, 1964](#)) which is approximately $+0.6\text{‰}\text{°C}^{-1}$ at intermediate and high latitudes but has a worldwide range of between $+0.2$ and $+0.7\text{‰}\text{°C}^{-1}$ ([Dansgaard, 1964](#)). Ideally,

it is important to establish the relationship between the oxygen isotope composition of precipitation (δp) and temperature at each site (see [Leng et al. \(2005a\)](#) and the IAEA-WMO Global Network of Isotopes in Precipitation (GNIP) database); it is worth noting here that a Dansgaard relationship is not common in coastal or monsoonal regions or where rainfall comes from two air masses.

For many lake records, the diatom oxygen isotope response to temperature will be dominated by the change in the isotope composition of precipitation and effectively ‘damped’ by the opposing effect of mineral-water fractionation. For diatoms, the measured isotope composition will, therefore, covary with temperature – with an increase of $\sim 0.1\text{--}0.4\text{‰}\text{°C}^{-1}$ (cf. [Leng and Marshall, 2004](#)). This assumes that $\delta p/dT$ always changes according to the Dansgaard relationship. It is usually very difficult to derive quantitative paleotemperature/ δp data with any certainty. It might be more realistic to use $\delta^{18}\text{O}_{\text{diatom}}$ in areas where there are likely to have been significant changes in the isotope composition of the lake water due to changes in

Figure 4 The fluorination line used at the NERC Isotope Geosciences Laboratory for the extraction of oxygen from diatom silica for isotope analysis was built by P.B. Greenwood.

the precipitation/evaporation balance or in the source of precipitation (see below). The change in $\delta^{18}\text{O}_{\text{diatom}}$ due to these factors is normally greater than temperature alone.

$\delta^{18}\text{O}_{\text{water}}$

Changes in the isotope composition of the lake water can be due to either evaporation or changes in the source of the rainfall. In closed (or terminal) lakes, evaporation of $\delta^{18}\text{O}_{\text{water}}$ will usually be far greater than changes due to temperature or δp . $\delta^{18}\text{O}_{\text{water}}$ depends on the balance between the isotope composition of inputs (including the source and amount of precipitation, surface runoff, and groundwater inflow) and outputs (evaporation and groundwater loss). Unless there is significant groundwater seepage, most closed lakes will lose water primarily through evaporation, the rate of which is controlled by wind speed, temperature, and humidity. The phase change of evaporation results in light isotopes of oxygen (^{16}O) being preferentially evaporated from water bodies leaving water that is relatively enriched in the heavier isotope (^{18}O). Any effects of varying precipitation source or temperature on $\delta^{18}\text{O}$ are often small in comparison to evaporative concentration and measured $\delta^{18}\text{O}$ (and δD) values become elevated above those of ambient precipitation. In extreme circumstances, evaporation in the lake catchment area or from the surface of a lake can lead to significantly elevated $\delta^{18}\text{O}_{\text{water}}$ values (Leng et al., 2005a).

The degree to which evaporation will increase $\delta^{18}\text{O}_{\text{water}}$ depends on the residence time of the lake (lake volume/throughput rate). Changes to a lake's residence time, caused

by changes in basin hydrology or varying groundwater fluxes, will also influence the degree of enrichment, as will changes in the nature of catchment vegetation and soils. These factors have been considered important in the interpretation of a $\delta^{18}\text{O}_{\text{diatom}}$ record from Lake Tilo in East Africa which is interpreted as changes in aridity (Lamb et al., 2005). They showed that high temperatures and a constant supply of solutes from hydrothermal springs enabled diatoms to grow throughout the year. The early Holocene lake level was close to the crater rim with a slow but progressive fall through the early Holocene. Major changes are recorded simultaneously by $\delta^{18}\text{O}_{\text{diatom}}$ and $\delta^{18}\text{O}_{\text{calcite}}$, although larger errors are associated with $\delta^{18}\text{O}_{\text{diatom}}$, and especially noteworthy is that the $\delta^{18}\text{O}_{\text{diatom}}$ data do not record the well-documented 7.8 ka BP arid interval found in neighboring Ethiopian lakes.

Certain diatom records have been shown to be sensitive to other aspects of climate, such as amount or source of precipitation. For example, abrupt shifts of up to 18‰ in $\delta^{18}\text{O}_{\text{diatom}}$ have been found in a 14 kyr-long record from two Alpine lakes on Mount Kenya (Barker et al., 2001), which cannot be entirely temperature related given the current knowledge of the diatom-temperature fractionation. Instead, the variations have been interpreted as a moisture balance effect related to changes in Indian Ocean SST through the Holocene. Episodes of heavy convective precipitation in the $\delta^{18}\text{O}_{\text{diatom}}$ record correlate with enhanced alkenone-based SST estimates.

There have been several studies of $\delta^{18}\text{O}_{\text{diatom}}$ from lakes in Northern Europe (see Jonsson et al., 2010; Leng and Barker, 2006). These lakes have similarities, in that many are open,

Figure 5 Controls on the oxygen isotope composition of diatom silica ($\delta^{18}\text{O}_{\text{diatom}}$). If precipitated in isotopic equilibrium, $\delta^{18}\text{O}_{\text{diatom}}$ depends entirely on temperature and the isotope composition of the lake water ($\delta^{18}\text{O}_{\text{water}}$). Disequilibrium effects, commonly known as 'vital effects' in biogenic precipitates, caused by local changes in microenvironment or rate of precipitation can induce systematic or nonsystematic offsets in the $\delta^{18}\text{O}_{\text{diatom}}$ signal. Interpretation of $\delta^{18}\text{O}_{\text{diatom}}$ in terms of temperature depends on knowledge of the environment and time of year in which the diatom silica forms. For example, at high-latitude sites, diatoms typically grow in the summer months in the surface waters. Quantitative interpretation similarly demands an understanding of the local controls on the isotope composition of the ambient water ($\delta^{18}\text{O}_{\text{water}}$). In marine localities, changes in $\delta^{18}\text{O}_{\text{water}}$ are primarily driven by changes in global ice volume, ocean currents, and meltwater inputs. In some lakes, there is a simple relationship to $\delta^{18}\text{O}_{\text{precipitation}}$, but in others the water composition is strongly influenced by processes such as evaporation within the catchment and within the lake itself. $\delta^{18}\text{O}_{\text{precipitation}}$ is increasingly being shown to be an important indicator of climate change: it typically changes with mean annual temperature, but nonlinear responses to climate change are increasingly being recognized. See text for more discussion of this figure. Adapted from Leng MJ and Barker PA (2006) A review of the oxygen isotope composition of lacustrine diatom silica for palaeoclimate reconstruction. *Earth Science Reviews* 75: 5–27.

through-flow systems with minimal evaporation. Changes in the stratigraphic record of $\delta^{18}\text{O}_{\text{diatom}}$ are interpreted as changes in the summer isotope composition of the lake water. In Northern Sweden, a 5000-year $\delta^{18}\text{O}_{\text{diatom}}$ record from a proglacial lake showed a general lowering trend of 3.5‰ with spikes of >1‰ and a ~1000-year cyclicity associated with sedimentary proxies for glacial advance. The authors suggest that a persistent change in the atmospheric circulation pattern could potentially have caused the changes in $\delta^{18}\text{O}_{\text{diatom}}$ because different air masses influence this area and these air masses have characteristic $\delta^{18}\text{O}$ signatures of their precipitation. They infer a steady increase but fluctuating dominance of colder and $\delta^{18}\text{O}$ -depleted air masses from the north/northeast. The $\delta^{18}\text{O}_{\text{diatom}}$ depletion and glacier events occur at times of relative ice rafted debris maxima in the North Atlantic, consistent with cold conditions and changes in surface wind directions. The Northern European studies show some similarities in the diatom isotope records, in particular, a late Holocene cooling, although there are regional differences, notably the relatively cold early Holocene on the Kola Peninsula is not seen in the records from Northern Sweden.

Changes in the source of precipitation have also been suggested as one reason for variations in $\delta^{18}\text{O}_{\text{diatom}}$ in a small,

spring fed lake in the Central Mexican highlands (Leng et al., 2005b). The lake has become more shallow, and today is at one of its lowest lake levels, but the modern isotope data suggest that the modern water is not evaporated, indicating that hydrology or recharge rates, rather than evaporation is controlling lake level. Two main possibilities might have controlled variations in $\delta^{18}\text{O}$ in the past. Since Central Mexico gets rainfall that originates from the tropical Atlantic/Gulf of Mexico and also from both the tropical and extratropical Pacific (in summer and winter, respectively), the authors postulate that changes in $\delta^{18}\text{O}_{\text{precipitation}}$ are connected to temperature and salinity variations in the Gulf of Mexico and/or changing contributions from these two different air masses (Gulf of Mexico vs. Pacific-derived hurricanes).

There are only a few studies of oxygen isotope ratios in lacustrine diatom silica that are older than the Holocene; these include interglacial investigations in France (Rioul et al., 2001), investigations into the MIS 11 period in Lake Baikal (Mackay et al., 2008), and the late-glacial–Holocene sequence from Lake El'gygytyn in North East Siberia (Swann et al., 2010).

Marine reconstructions

In the marine environment, records of $\delta^{18}\text{O}_{\text{diatom}}$ can be used in a similar way to that of planktonic Foraminifera; $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_{\text{foram}}$) being sensitive to changes in both temperature and the $\delta^{18}\text{O}_{\text{water}}$ of surrounding water, a function of ocean currents/masses and riverine/continental/meltwater inputs. Accordingly, $\delta^{18}\text{O}_{\text{diatom}}$ can be employed as a direct replacement for $\delta^{18}\text{O}_{\text{foram}}$ in oceanic regions that are depleted in CaCO_3 and so do not preserve calcareous Foraminifera. Planktonic Foraminifera are capable of living at depths of hundreds of meters and, therefore, tend to have an isotopic signature typical of deep water, whereas diatoms are restricted to the surface ocean because of their need to photosynthesize, and, therefore, reflect isotopic conditions from the uppermost layers of the surface ocean.

Existing records of marine $\delta^{18}\text{O}_{\text{diatom}}$ primarily originate from high-latitude regions, such as the Southern Ocean, where Foraminifera are generally not well preserved in the sedimentary record. However, in one early study, records of $\delta^{18}\text{O}_{\text{diatom}}$ were obtained from the Gulf of California over the last 3 ka (Juillet-Leclerc and Schrader, 1987). By using modern-day oceanographic data to account for localized changes in $\delta^{18}\text{O}_{\text{water}}$, $\delta^{18}\text{O}_{\text{diatom}}$ was used to detect SST changes of up to 8 °C. In conjunction with taxonomic studies, cold SST were linked to changes in regional upwelling intensity, in turn tied to atmospheric patterns related to El Niño events. These results indicate a period of enhanced upwelling and intensified trade winds in North Pacific Ocean and reduced El Niño activity between 1.5 and 2.0 ka BP. Subsequent work focusing on the last 100 years has verified these findings by revealing a strong relationship between $\delta^{18}\text{O}_{\text{diatom}}$ and historical records of El Niño events (Juillet-Leclerc et al., 1991).

Combined $\delta^{18}\text{O}_{\text{diatom}}/\delta^{18}\text{O}_{\text{foram}}$ studies

Where both diatoms and Foraminifera co-occur, $\delta^{18}\text{O}_{\text{diatom}}$ and $\delta^{18}\text{O}_{\text{foram}}$ can be combined to provide unique insights

into paleoceanographic conditions. For example, Shemesh et al. (1992) combined $\delta^{18}\text{O}_{\text{diatom}}$ with planktonic $\delta^{18}\text{O}_{\text{foram}}$ to account for variations in $\delta^{18}\text{O}$ that arose from changes in global ice volume. By assuming that the incorporation of oxygen into the Foraminifera calcite shell and diatom frustule occurred in the same season and water depth and using $\delta^{18}\text{O}$ –temperature coefficients for diatoms and Foraminifera, an $\sim 2.0^\circ\text{C}$ SST increase was observed in Southern Ocean surface waters during the shift from glacial to Holocene conditions with a concordant 1.2‰ decrease in $\delta^{18}\text{O}_{\text{water}}$. Records of $\delta^{18}\text{O}_{\text{diatom}}$ and planktonic $\delta^{18}\text{O}_{\text{foram}}$ have also been combined in the subarctic North West Pacific Ocean during the late Pliocene (Haug et al., 2005). On the basis of modern-day data, the Foraminifera were assumed to have lived and precipitated their shells during the spring months, whereas the diatoms were primarily blooming during autumn/early winter (Swann et al., 2006). Divergent trends in the two records at the intensification of Northern Hemisphere Glaciation (~ 2.75 – 2.73 Ma) are, therefore, interpreted as reflecting interseasonal conditions with increases in $\delta^{18}\text{O}_{\text{foram}}$ suggesting a significant, 7.5°C , cooling of the spring surface waters while a 4.6‰ decrease in $\delta^{18}\text{O}_{\text{diatom}}$ equated to a significant freshening and warming of the autumn surface waters related to the development of a halocline (salinity driven, stratification boundary).

Meltwater

Other records of $\delta^{18}\text{O}_{\text{diatom}}$ have documented notable changes in surface water $\delta^{18}\text{O}$ arising from meltwater influx. Results from the Atlantic and Indian sectors of the Southern Ocean have demonstrated periodic decreases of ~ 1 ‰ in the Holocene, changes of up to 2–3‰ during the last glacial and 5‰ variations over the last 430 000 years (Shemesh et al., 1994, 1995, 2002). Relating these changes to temperature contradicts other proxy records for temperature from this region. Instead, the periodic marked decreases in $\delta^{18}\text{O}_{\text{diatom}}$ are thought to be connected to meltwater influxes originating from Antarctica, releasing water containing an inherently lower $\delta^{18}\text{O}$ than seawater (Shemesh et al., 1995). While these studies highlight the potential sensitivity of the Southern Ocean to meltwater fluxes from Antarctica, it is not currently possible to fully understand the timing, mechanism, or implication of these meltwater releases due to the low resolution nature of the $\delta^{18}\text{O}_{\text{diatom}}$ records.

Records from the North Pacific Ocean and Bering Sea have also shown significant changes in meltwater influx. Using mixed species samples, Sancetta et al. (1985) detected 5–10‰ variations in the Bering Sea over the last glacial cycle. By using changes in the sedimentary diatom assemblages to distinguish between changes in SST and salinity, the isotope variations were partitioned to reflect changes in both sea-ice extent as well as meltwater influx with a 1.9‰ equivalent increase in SST between the last glacial and the present day. Further south in the subarctic North West Pacific Ocean, large changes of ~ 4 ‰ are apparent over a series of glacial–interglacial cycles during the late Pliocene and Early Quaternary (Swann, 2010). By accounting for other processes that may alter $\delta^{18}\text{O}_{\text{diatom}}$ such as temperature, changes in global ice volume, and freshwater inputs from other sources, these changes were related to meltwater input from glacials surrounding the North Pacific and Bering Sea basins over similar timescales.

Conclusions

Since fluorination and other analytical techniques will liberate oxygen from all the components in the sediment, analysis of the oxygen isotope composition of diatom silica requires samples that are almost pure diatomite. There is a generally acceptable protocol involving chemistry, sieving and settling techniques, and more recently laminar flow separation for extracting clean diatoms for isotope analysis. However, all samples require a dedicated procedure and every sample must be scrutinized with microscopy. Diatom silica analysis requires the removal of the outer hydrous layer before a reaction to break the tetrahedrally bonded silica skeleton (Si—O—Si). To date, there are four main methods (both thermal dehydration, isotope exchange, and stepped fluorination techniques) to do this.

Diatom $\delta^{18}\text{O}$ in sediments can be an extremely useful indicator of paleoenvironmental change and tends to be most successful in areas where there are likely to have been large changes in the isotope composition of the host water. In lakes, this can be due to changes in the precipitation/evaporation balance, or source of precipitation, and in oceans it can be due to variations in meltwater flux. The change in $\delta^{18}\text{O}_{\text{diatom}}$ due to these factors is normally greater than temperature and methodological errors.

As with all isotope studies, the use of $\delta^{18}\text{O}_{\text{diatom}}$ in paleoenvironmental studies should include a study of the contemporary environment and the modern diatom silica. The presence of a systematic relationship between temperature, water isotope composition, and diatom isotope composition for the host water enables quantitative interpretation of the sediment record. It is particularly useful to know when and where the diatom silica ‘bloom’ occurs in the modern environment, so details of diatom ecology are important. Modern studies will tell us whether the diatom record reflects specific seasons or year-round conditions.

Introduction

Diatoms are single-celled, microscopic algae (Bacillariophyta) whose siliceous, glass-like cell walls preserve well in various sedimentary environments allowing reconstructions of past environments from subfossil diatom assemblages. They are a very successful group of organisms that can be found in virtually every aquatic habitat. Accordingly, diatom analysis is applicable across a wide range of aquatic ecosystem types, including freshwater, brackish, estuarine, and ocean, and includes lentic and lotic environments, wetlands and their associated damp, marginal, and littoral zones. This is why diatoms are one of the most widely used biological indicators in Quaternary paleoecology (Stoermer and Smol, 1999; see Overview).

Diatoms have played an important role in providing information on a wide spectrum of past environmental and ecological changes, such as climatic and lake-level changes, water pollution, eutrophication, and acidification, while their usefulness is also demonstrated in archaeology, oil and gas exploration, and forensic science (Stoermer and Smol, 1999 and Battarbee et al., 2001; see Use in Archaeology). Most studies using fossil diatoms as indicators of environmental change have focused on the Late Glacial and Holocene sequences, although long diatom records encompassing several glacial-interglacial cycles are available from marine and freshwater sequences (e.g., see North Atlantic and Arctic; Large Lakes) and offer great potential for a very long-term perspective of environmental change. The standard method of inferring environmental conditions from fossil diatoms consists of an analysis of assemblage composition and consideration of the relevant autecological characteristics of the taxa present (indicator species). In recent decades, tremendous progress has been made in our methods of interpreting diatom stratigraphical data through powerful numerical techniques that allow surprisingly accurate quantitative reconstructions of environmental change to be made.

Why Are Diatoms Good Paleoindicators?

There are many reasons why diatoms are such excellent paleoindicators in Quaternary studies (Dixit et al., 1992 and Stoermer and Smol, 1999):

- Diatoms comprise a large proportion of total algal biomass in various aquatic systems and their assemblages are typically taxon rich. The large number of taxa enhances the ecological information gained, and hence increases the confidence of environmental inferences.
- They collectively show a broad range of tolerance along environmental and ecological gradients, with individual

species having specific ecological and water quality requirements that are usually quantifiable.

- They have one of the shortest generation times of all biological indicators (~2 weeks), for which reason they reproduce and respond rapidly to environmental change.
- They are characterized by having an opaline, siliceous frustule that is resistant to degradation and hence is well preserved in different sedimentary environments.
- The taxonomy of diatoms is comprehensively documented, allowing species or even subspecies level identification of fossil diatom assemblages.

Analytic and Interpretative Procedures

Diatom Concentrations and Accumulation Rates

A prerequisite for the correct interpretation of stratigraphic diatom data is the careful collection, processing, and analysis of the initial diatom samples. Sampling and laboratory methods are discussed in detail by Battarbee et al. (2001). Diatom counts from sediments are most often expressed as percentage values, and paleoecologists generally base their environmental reconstructions on the assumption (that may not always be valid) that the percentage composition of diatoms in sediment assemblages accurately reflects the relative abundance of different taxa across the different living communities in the lake. Such proportional data lend themselves well to most numerical data treatment procedures and quantitative approaches. Estimation of diatom concentrations per unit weight (frustules per gram dry weight⁻¹) or unit volume (frustules cm⁻³) can be used as a record of diatom paleoproductivity and possibly to indicate net primary productivity. If diatom concentrations are required, an easy method is to add a known quantity of external markers (e.g., microspheres) in cleaned sediment slurry (Battarbee et al., 2001). Diatom concentration values *per se* have rather limited use in paleoecology, but they can be further converted to diatom accumulation rates (DAR; frustules per cm² per year, also referred to as diatom valve flux; Fig. 1). However, an excellent chronology is needed for this.

One has to bear in mind that different factors such as diatom preservation status (i.e., dissolution and diatom fragmentation during grazing or sample preparation) as well as potential variations in the rate of sediment accumulation, make interpretation of diatom concentration results more-or-less tentative. Also, because diatom cell sizes vary tremendously, simple concentrations may produce a misleading depiction of total diatom productivity. To minimize such biases, species-specific correction factors can be developed that allow the composition of the source populations to be reconstructed. Also, diatom concentrations can be converted into biovolumes per cm per year, using taxon-specific measurements of whole-cell volumes. Surprisingly, the latter approach

Figure 1 Records of total planktonic diatom flux (valves $\text{cm}^{-2} \text{yr}^{-1}$) and most important individual species fluxes from a 140 m long core taken from Lake Biwa, Shiga Prefecture, Japan, covering ca. 140 ka. The dashed line indicates the present level of diatom flux for the total planktonic taxa and each individual taxa, respectively. Based on characteristics of past and modern diatom responses to possible climate variables, the authors interpreted changes in total planktonic diatom flux to reflect a combination of summer precipitation, winter temperature, and snowfall values. During the 140–101 ka interval, high values of *Stephanodiscus suzukii* productivity and the disappearance of *Aulacoseira nipponica* were interpreted to indicate weaker vertical mixing, possibly caused by increased temperatures and decreased snowfall levels in winter. During the 101–70 ka interval, the record showed levels near or above those observed in present times, indicating that winter water temperatures fell within the optimal range for *A. nipponica* to prosper. Low *Aulacoseira* fluxes during the 70–7 ka interval were interpreted to indicate weak winter vertical mixing and cold winters. From Kuwae M, Yoshikawa S, Tsugeki N, and Inouchi Y (2004) Reconstruction of a climate record for the past 140 ka based on diatom valve flux data from Lake Biwa, Japan. *Journal of Paleolimnology* 32: 19–39.

has rarely been implemented in fossil data, despite the fact that algal biovolumes have long been a standard and routine unit of measure in modern phytoplankton ecology. The concentration estimates can be further reinforced by multiple core and multiple indicator analyses. In conjunction with diatom studies, analysis of fossil pigments, organic carbon and chemical determination of biogenic silica may help reconstruct the biomass of diatom populations in a more reliable way. For example, Abrantes (2000) compared DAR records from several Atlantic upwelling sites with other independent productivity proxies such as silicoflagellates, radiolaria, total opal, and abundances and accumulation rates of organic carbon and benthic Foraminifera, and suggested that maximum productivity of the past 200 ka in the eastern Atlantic occurred at the Last Glacial Maximum (LGM), consistent with the models that attribute glacial atmospheric CO_2 decrease to higher low-latitude productivity.

Ecological and Habitat Classification – Qualitative Approaches

Despite the rapid development of quantitative reconstruction techniques during the past few decades, qualitative interpretations based on the relevant autecological characteristics of the individual taxa and the habitat and ecological classification of

groups of taxa still form the basis for understanding and interpreting the stratigraphic diatom record. Many diatom species have clearly defined, and relatively narrow, preferences for particular habitats and water quality conditions. These species are indicative of several variables, including nutrient availability, acidity, light and thermal conditions, dissolved oxygen concentrations, and lake levels. As a result, a broad range of specific paleoenvironmental interpretations can be made on the basis of the life histories, habitats, and known ecological preferences of indicator species. Interpretation of diatom records is fortunate in this respect, because there is a considerable amount of tested species ecological data available. In particular, categorization of diatom taxa according to their acidity or salinity tolerances has been successfully used to interpret changes in surface water acidity, sea level, and hydrology of saline lakes (see, e.g., Palmer and Abbott (1986) and Stoermer and Smol (1999)).

Diatom species also have affinities for particular physical habitats for example there are open water (planktonic) and benthic forms. See [Diatom Introduction](#) for more details. In stratigraphic studies dealing with dynamic coastal environments, classification of diatoms according to habitat has also proved very useful since there are distinct communities associated with the different salt-marsh habitats ([Fig. 2](#)).

Qualitative interpretations based on expert knowledge have both advantages and disadvantages. Qualitative approaches

Figure 2 Idealized scheme of some possible diatom assemblage shifts occurring at the transgressive overlap of a peat with tidal deposits under different drainage conditions. Accuracy of paleotidal inference decreases to the right. Note that the relative representation of different groups will vary according to local conditions and input of external (allochthonous) material. From Denys L and De Wolf H (1999) *Diatoms as indicators of coastal paleoenvironmental and relative sea-level change*. In: Stoermer EF and Smol JP (eds.) *The Diatoms: Applications for the Environmental and Earth Sciences*, pp. 277–297. Cambridge: Cambridge University Press.

may pursue a variety of theory-generating aims, including identifying potentially important variables or concepts, recognizing patterns and relationships, and generating coherent theories and hypotheses. However, qualitative studies rely heavily on subjective interpretation and expert knowledge. They do not typically generate answers but rather provide narrative accounts.

Toward More Objective Assessment

A great variety of classification and descriptive multivariate tools have been developed that can be used to more effectively manage the rich mosaic of ecological information inherent in diatom stratigraphic data. Typically, an important first step is the partitioning or zoning of the initial diatom diagram with the aim of identifying uniform segments in the data. A favored method for paleoecological data has been the constrained incremental sum-of-squares clustering (CONISS; Grimm, (1987)). However, it suffers from having no numerical basis for deciding on the number of reliable or statistically significant zones within a sequence. Bennett (1996) has resolved the problem by using the broken-stick and randomization models to assess the reliability of different zonations against a model of random distribution of zones within a sequence. For example, Korhola and Weckström (2004) applied Bennett's broken-stick model to core data from several lakes in Finnish Lapland to identify stratigraphic levels in which diatom floristic changes have been most distinct. Such analysis helped them elucidate

the relative role of local versus regional environmental changes in explaining the changes in fossil diatom assemblages. However, Bennett's method for determining the number of zones is based on the use of a single randomized sample as a comparison. Techniques that use a large set of randomized samples might provide more realistic means of making statistical evaluation of possible zonations.

Ordination techniques can be used to arrange species and/or samples along gradients. Ordination is especially useful for visualizing large and complex data sets in reduced dimensions that are ecologically easier to interpret. For example, stratigraphic sample scores derived from an indirect gradient analysis technique can be plotted chronologically, and when related together with species scores to ordination axes, used to determine the major ecological drivers of the temporal variation. Stager et al. (1997) used correspondence analysis (CA) to show that changes in the fossil diatom assemblages of a core from Lake Victoria occurred in response to climatic fluctuations during the Holocene. First, a CA ordination biplot of major diatom taxa distributed them into qualitative assemblage groups by quadrant (Fig. 3A). Based on available diatom habitat information, axis 1 was interpreted to approximate a gradient of water column stability and axis 2 to approximate a gradient of precipitation:evaporation (P:E) ratios or lake depth. When plotted stratigraphically, the sample scores of the two first CA axes were then able to be used as proxies of windiness, rainfall patterns, and monsoon variability (Fig. 3B). Large Lakes gives a more detailed account of the Lake Victoria diatom record and its use in paleoclimatic reconstruction.

Figure 3 Interpretation of a diatom record of a core from Lake Victoria's Damba Channel. (a) CA biplot showing major diatom taxa of the core. (b) CA axis plots and pollen stratigraphy. Inverted CA axis 1 represents water column stability and resembles the *Celtis* (seasonally dry forest) pollen record. CA axis 2 represents P:E or lake depth, and resembles the Moraceae (moist forest) pollen record. Horizontal dotted lines mark present conditions. Vertical dotted lines delimit diatom zone boundaries. From Stager et al. (1997).

Ordination procedures can also aid in the comparison and synthesis of multiple data sets. For example, Sorvari et al. (2002) summarized the diatom records from several short cores from Arctic Lapland using principal components analysis (PCA), and showed that the changes in diatom assemblages were significantly correlated with long-term variations in regional spring temperatures. Smol et al. (2005) used

detrended canonical correspondence analysis (DCCA) to summarize the amount of species turnover in paleolimnological records (mostly diatoms) from 55 lakes in the circumpolar Arctic. They found widespread, parallel changes in species compositions that were likely to be driven by climate warming.

The multiple proxy indicator approach enables some independent variables representing different environmental

processes to be identified. Variance decomposition (Borcard et al., 1992) can then be effectively used to distinguish the independence and relative strength of different variables in explaining diatom species compositional changes through time. In each variance partitioning experiment, the diatoms are the response variable and other independent variables are used in different combinations as explanatory variables. The effect of time-dependent ecological and environmental processes can be further removed by introducing sample age as a covariable in all experiments. Finally, a variance decomposition experiment is performed with each of the predictor variables assigned as covariables to cancel out their effect on one another and assess redundancy proportions between variables. The explanatory strength of various variables (or their combinations) is assessed by testing the significance of the first ordination axis under different model conditions using a constrained Monte Carlo permutation test. For example, Barker et al. (2000) used partial redundancy analysis (RDA) to test whether the effect of tephra deposition 1.19 ka had a statistically significant impact on the diatom assemblages in Lake Massoko, a volcanic crater lake in southern Tanzania, and discriminated between floral changes in response to tephra and changes in climate (as derived from the pollen data), or those induced by physical catchment disturbance (as revealed by the magnetic properties of the sediment).

Given a modern reference data set (see below), canonical ordination can also be a useful visual aid in environmental reconstruction. Fossil diatom assemblages can be introduced in the ordination analysis of modern diatom data as

supplementary (passive) samples and hence positioned into the ordination plane of modern training set samples on the basis of similarities in their biological composition. Changes in the diatom assemblages within a core can therefore be compared directly to the diatom-environment gradients within the modern data set to follow core trajectories. Engstrom et al. (2000) used this methodology effectively when studying chemical and biological trends during lake evolution in Glacier Bay, Alaska (Fig. 4). They summarized the limnological trends in lakes of varying age by projecting their fossil diatom assemblages onto the DCCA biplot of the modern samples. The core data of most lakes showed a net negative trajectory along DCCA axis 1, suggesting that the main trend of lake development with increasing age was a progressive loss of pH, alkalinity, and base cations, and a corresponding increase in dissolved organic carbon (DOC).

Diatom core data can be subjected to several numerical data manipulations to evaluate diatom community stability and diversity. For the former, rate of change analysis (Jacobson and Grimm, 1986) has proved useful (Figures 5 and 9). This technique simply calculates the dissimilarity between successive samples divided by the estimated period of deposition elapsed between the two, in order to produce measures of any assemblage changes per unit time. Chord distance is the dissimilarity metric most commonly applied to diatom data because of its statistical properties concerning the weighting of species with low percentages. The rate of change method is critically dependent on the time standardization unit (TSU) used to standardize the estimated dissimilarity, so good

Figure 4 Detrended canonical correspondence analysis of modern and fossil diatom assemblages from the chronosequence of lakes in the Glacier Bay region of southeastern Alaska. In the inset, ordination of modern diatom assemblages (from surface sediments) and associated water-chemistry data are shown. The arrows depict the direction of increase and maximum variation of the measured environmental variables. Lakes plotting close to one another have similar diatom composition. In the main figure, the time-trajectories from 10 sediment cores (B, bottom; T, top) were projected onto the biplot by adding the core assemblages to the analysis as passive samples. From Engstrom et al. (2000).

Figure 5 Diatom diversity as assessed by rarefaction analysis and rate of diatom assemblage change in the annually laminated sediment of Baldeggersee, Switzerland, between 1885 and 1993. The diatom diversity closely mirrors the different phases of nutrient enrichment in the lake with decreasing numbers of taxa during the eutrophication phases (cf. Fig. 9). The timing and direction of diatom assemblage changes also compare well with sedimentological and limnological changes (cf. Fig. 9). The error bars in the rarefaction diagram represent the 95% confidence interval, whereas the dashed line in the rates of change diagram indicates the approximate significance level (2.5th percentile). The line through the rarefaction estimates is based on a LOWESS smoother. From Lotter AF (1998) *The recent eutrophication of Badeggersee (Switzerland) as assessed by fossil diatom assemblages. The Holocene* 8: 395–405.

chronological control is essential for this. As sediment accumulation rates are variable, sample intervals are unequally distributed through time. In order to correct this systematic bias, re-sampling by interpolation of new samples at even time intervals can be done. The resulting synthetic data set can then be subjected to smoothing and the chord distance coefficient calculated (Laird et al., 1998). When analyzing large and complex data matrices, such as the multitaxon diatom core data sets, often are, it is sometimes necessary to reduce the dimensionality in the data (e.g., by PCA) prior to estimating the rates of change (Barker et al., 2000).

The assessment of past ecological diversity as deduced from the sedimentary record is a challenging task. Besides variables such as differential preservation of diatom fossils, one of the major issues in assessing past diversity is the choice of a sound measure that takes into account richness and equitability. The diversity of subfossil organisms cannot be investigated unless the count size of the samples is constant or standardized, because the number of identified taxa usually increases as the fossil count size increases. Rarefaction analysis (Heck et al., 1975) has been shown to be very suitable for fossil diatom data (Fig. 5). Rarefaction uses a strategy of random selection without replacement, typically selecting a sample of the same size as the smallest count from the entire population. In this way realistic estimates of richness are produced without any bias associated with the variability of individual sample count

sizes. However, when dealing with non-laminated sediments, differences in sediment accumulation rate need further to be taken into account when interpreting the diversity records.

Estimating Parameter Values Using Diatoms

Numerical modeling, with the aim of quantitative paleoenvironmental reconstruction from diatom assemblages, was first applied to reconstruct pH. The early applications were based on ecological species categories and pH indices, and later multiple linear regression models were developed to estimate pH according to the proportions of the established pH-preference groups (see Battarbee and Charles, 1987 and Davis, 1987 for extensive reviews). More recently, paleoecologists have cataloged the ecological optima and tolerances of diatom assemblages and have constructed transfer functions that allow environmental conditions to be inferred from fossil assemblage data (Birks et al., 1990). Quantitative approaches using diatoms are now being applied to a wide array of environmental problems and questions, with many new methodologies currently being implemented.

In diatom paleoecology, transfer functions simply describe the relationship between diatom assemblages and their environment with the ultimate goal to use the present-day ecology of diatoms to quantitatively infer past conditions. The basic approach is illustrated as a hypothetical example in Figure 6. The transfer function approach involves two steps: (1) the regression step in which the responses of taxa to the contemporary environment are modeled, and (2) a calibration step in which the environmental variable of interest is predicted from the fossil compositional data. Transfer functions are established using modern diatom assemblages and measured environmental variables from a calibration data set (also called a training set; Fig. 6A). These calibration sets involve sampling a range of sites (e.g., lakes, wetlands, estuaries, marine environments, usually >40 sites) for a suite of critically considered environmental variables, which are then related to the diatom assemblages preserved in the surface sediments (top 0.5–1 cm representing the last few years of sediment accumulation) of the systems concerned using various numerical procedures (Fig. 6B). The transfer function approach is based on the implicit assumption that the modern training sets cover the range of environmental conditions likely to be represented by the fossil assemblages. Hence, calibration data sets should ideally span all biologically relevant environmental gradients.

The mathematical methods for establishing a transfer function are commonly based on nonlinear regression techniques. The most popular approaches in diatom studies have been weighted averaging (WA; ter Braak and van Dam (1989)) and the WA partial least squares (WAPLS; ter Braak and Juggins (1993)) regression, because they perform well with noisy, species-rich, compositional data, with many zero values and some rogue observations (outliers). In both methods, the underlying response model is the Gaussian function, that is, each taxon has a bell shape (Gaussian) distribution along an environmental variable. From the Gaussian curve, the species optimum (the peak) and its tolerance (the standard deviation) can be estimated (Fig. 7).

Figure 6 Simplified illustration of the typical steps involved in developing and assessing the predictive ability of a diatom-based calibration model and its application to fossil diatom data including: (a) selection of a modern training data set; (b) estimation of taxon responses based on their distribution in the training set (regression); (c) generation of a transfer function on the basis of the training set (calibration); (d) selection of an independent test set to assess the transfer function (calibration); (e) use of computer re-sampling techniques, such as jackknifing or bootstrapping, to assess the transfer function (calibration); and (f) reconstruction of parameter value from fossil diatom assemblages and estimation of sample-specific prediction errors by bootstrapping. Modified from Fritz et al. (1999) Fritz SC, Cumming BF, Gasse F, and Laird KR (1997) Diatoms as indicators of hydrologic and climatic change in saline lakes. In: Stoermer EF and Smol JP (eds.) *The Diatoms: Applications for the Environmental and Earth Sciences*, pp. 41–72. Cambridge: Cambridge University Press.

Figure 7 Gaussian response curve for the changing abundance of a species along an environmental gradient. t = tolerance; u = optimum; c = maximum. From ter Braak CJF (1987) *Unimodal Models to Relate Species to Environment*, 152pp. Unpublished PhD Thesis, University of Wageningen.

In the WA methods, the estimate for the species optimum (u_k) is obtained as the average of the k th taxon in the calibration dataset (y_{ik}) weighted by the environmental variable (x_i) of interest:

$$\hat{u}_k = \frac{\sum_{i=1}^n y_{ik} x_i}{\sum_{i=1}^n y_{ik}} \quad [1]$$

WA can also be used to estimate tolerance values (Fig. 7) for diatoms and these values can be used to down-weight the importance of taxa with a wide tolerance relative to those with a narrow tolerance. Figure 8 shows the response models and the estimated WA temperature optima and tolerances of the most frequent diatom genera and species for the Arctic Lapland temperature training set. These estimated optima and tolerances form the transfer function, which can then be used to infer past temperature from fossil diatom assemblages.

In addition to WA, other routinely used calibration techniques include the maximum likelihood (ML), modern analog technique (MAT), and Gaussian logit regression (GLR) (reviewed in Birks, 1995 and Birks, 1998). Recently, artificial neural networks (ANNs) have been introduced to diatom paleoecological research. However, Telford and Birks (2005) found that transfer functions based on a unimodal species–environment response are more robust to spatial autocorrelation of environmental variables in the training set (a serious problem for transfer functions) than MAT or ANN models, which are likely to over-fit the data unless a spatially independent test set (see below) is available to help model selection. Of other novel techniques, Bayesian inference is shown to have many advantages over conventional frequency distribution methods in environmental reconstruction, including reduction of inherent systematic bias, more precise error estimation, the possibility of utilizing existing ecological and environmental information, and improved extrapolation capacity (Toivonen et al., 2001; Vasko et al., 2000; Korhola et al., 2002).

Different modeling tools have their inherent philosophical and mathematical assumptions as well as limitations, so the prediction ability of the transfer models must be carefully evaluated. Ideally, independent data sets that are similar in size and environmental gradients would best suit this purpose

(Fig. 6D), but are seldom available because they are laborious and expensive to collect. Instead, computer-intensive re-sampling techniques, such as jackknifing (leaving one-out substitution) and bootstrapping (creation of pseudoreplicate data sets by re-sampling), are used (Fig. 6E); these should provide more realistic assessments of the prediction ability of a transfer model than the pure or apparent error (Fig. 6C). The output of the reconstruction procedure will be a reconstructed parameter value for each core sample plus sample-specific prediction errors, commonly estimated by bootstrapping (Fig. 6F).

Evaluation of the Reconstruction

There are no means or ‘skilled techniques’ to prove that a reconstruction is correct. The most robust evaluation is to compare diatom-inferred values with measured long-term data series where these exist (Figures 9 and 10). Close agreement between reconstructed and measured values increases confidence in the reconstruction whereas deviation between the two sets of data warrants caution. However, close agreement during the monitoring period does not necessarily imply accurate reconstructions for earlier periods, especially if assemblages have a very different composition. Conversely, divergence for the monitoring period does not necessarily imply that reconstructions for earlier periods are in error.

Another way to evaluate the robustness of a diatom-based reconstruction is to compare the inferred values with the ones reconstructed using other proxy sources (Fig. 9). Close agreement between several proxy indicators increases their reliability. In addition, indirect gradient analysis (PCA, CA, and DCA) can be used to determine whether the inferred environmental variable is related to the main directions of variation in the fossil diatom assemblages (i.e., the sample scores on the first unconstrained axis). The strength of the correlation between the unconstrained axis 1 sample scores and the inferred values indicates the extent to which the principal changes in diatom community structure can be explained by the inferences of the parameter in question.

Implicit in the transfer function approach is that the modern training set samples provide good analogs for the fossil diatom assemblages. This could simply be done by highlighting sediment samples that contain significant numbers of taxa that are absent from the training set. A more robust assessment is to find the closest modern analogs for each fossil sample using MAT (Fig. 9). MAT quantifies the dissimilarity between modern and fossil samples using various distance measures. Another way is to assess the goodness-of-fit between modern and fossil species data using constrained canonical correspondence analysis (CCA) with the variable of interest as the sole constraint. A fossil sample with a residual distance equal to or larger than the residual distance of the extreme 10% of the calibration data set is typically considered to have a poor fit to the desired variable (Birks et al., 1990).

Here are two examples in which multiple data manipulation and validation tools have been efficiently used to extract information from fossil diatoms. Wolfe (2003) examined different methods of interpreting diatom stratigraphic data from the late Holocene sediments of a small Arctic lake on Baffin Island, Nunavut, Canada, with the objective of gaining

Figure 8 Responses of diatoms to the site-specific air temperature from a training set of 64 lakes in Arctic Lapland. (a) Distribution of the most dominant diatom genera along the temperature gradient. The estimated weighted averaging (WA) temperature optimum for each genus is indicated as a tick. The trend lines are based on a Gaussian logit model. (b) The estimated temperature optima (solid squares) and tolerances (bars) of the 40 most abundant diatom taxa in the data set arranged according to temperature optima. From Weckström J and Korkola A (2001) Patterns in the distribution, composition and diversity of diatom assemblages in relation to ecoclimatic factors in Arctic Lapland. *Journal of Biogeography*, 28, 31–46.

paleoclimatic insights from fossil assemblages. In this study, diatom relative frequencies and absolute abundances were subjected to several data manipulations, including application of a WA transfer function for summer water temperature, conversion of valve concentrations to cell biovolumes, biostratigraphic rate of change, and taxonomic richness estimated by rarefaction analysis. Hence, from the primary diatom data, a

second data set was derived on the basis of the data manipulations, consisting of seven new variables. The major directions of variability within the derived diatom data were then summarized using PCA and the results were considered in relation to independent paleoclimatic proxies to enable an objective assessment of the response of freshwater diatom communities to climatic change.

Figure 9 Measured total phosphorus (TP) during spring circulation (filled circles) compared to diatom-inferred TP values and median grain-size distribution in the Baldeggersee annual layers. The horizontal lines represent the annual TP range in the uppermost 15 m of the water column. The dots on the right hand side of the graph represent samples with close (filled dots; 2nd percentile) and good modern analogs (open dots; 5th percentile). Grain-size analyses in annual layers show variations in calcite size (a proxy for PO_4 concentration in the lake water) that parallel the diatom-inferred TP concentrations, hence giving independent support to the reconstruction. From Lotter AF (1998) The recent eutrophication of Badeggersee (Switzerland) as assessed by fossil diatom assemblages. *The Holocene* 8: 395–405.

The second example comes from Laajalahti, a semi-enclosed embayment of the eastern Baltic Sea that has been studied for diatoms to reconstruct its eutrophication history (Weckström et al., 2004). Figure 10 shows the summary diatom diagram, together with diatom-inferred total dissolved nitrogen (TDN) concentrations, diversity estimates, analog measures, and monitoring data of TN for the last 30 yr (Weckström et al., 2004). The diagram shows the transition from a flora dominated by benthic *Fragilaria* taxa in the late nineteenth century to one dominated by a succession of planktonic *Cyclotella* and *Thalassiosira* species today. All fossil samples in this case have squared chord distances less than 10% of the distribution of all distances among modern samples in the calibration set, as assessed by MAT, suggesting that the samples have good floristic analogs in the eastern Baltic training set. However, one sample had a poor fit to TDN as assessed by the constrained CCA. Comparison between the reconstructed values and monitoring data show that the transfer function is able to reproduce trends and absolute values for the last ca. 10 yr but underestimates concentrations during the most eutrophic period during the 1970s. This underestimation is probably due to the lack of high TN sites in the training set. The down core diversity of diatoms closely follows the pattern of eutrophication deduced from the diatom TDN transfer function. As expected, the diversity decreases with increasing concentrations on TDN, following a negative logarithmic function. These patterns give clear evidence that nutrient enrichment leads to a loss in diatom diversity at this site. There is more variability in the species richness than in the overall species compositions (as deduced on the basis of DCA). These patterns

Figure 10 Summary diatom diagram showing major diatom taxa, proportion of planktonic taxa, detrended correspondence analysis (DCA) axis 1 scores, rarefaction species richness, diatom-inferred annual mean TDN and measured TN concentrations for Laajalahti embayment, Helsinki. The inferred TDN values are based on the two-component WAPLS model. The measured TN concentrations are presented as annual, seasonally weighted mean values. The sole sample having a poor CCA fit to TDN is shown by asterisk. Modified from Weckström K, Juggins S, and Korhola A (2004) Quantifying background nutrient concentrations in the coastal zone of the Baltic Sea. *Ambio* 33: 324–327 and Weckström K (2006) Assessing recent eutrophication in coastal waters of the Gulf of Finland (Baltic Sea) using subfossil diatoms. *Journal of Paleolimnology* 35: 571–592.

reinforce the general axiom that aquatic biological diversity tends to decrease with increasing nutrient levels.

Conclusions

Stratigraphic diatom data are complex, multivariate, and temporally ordered, most commonly forming irregularly spaced discontinuous time series. Such proxy data thus have special statistical properties and their numerical analysis requires techniques that take particular account of these unique data properties. Much progress has been made in the development of quantitative approaches to infer environmental variables from diatom assemblages. Robust diatom-based quantitative transfer functions have been created for pH, nutrients, salinity, organic carbon, water and air temperature, ice cover duration, lake level and other environmental parameters. However, quantitative inference techniques have their own shortcomings and limitations, so all transfer function approaches have to be assessed critically (Birks, 1998). We need to be sure that our interpretations are not becoming too mechanistic and straightforward, as the transfer functions will always produce results, whether correct or not. Also, it should be remembered that the transfer function approach is not the sole method for gleaning useful information from diatom stratigraphic data. As shown by the study of Wolfe (2003), highly valuable environmental information can be extracted from diatom stratigraphic data when subjected to many kinds of creative numerical data manipulations. Other indicators that can be measured in sediments will further strengthen conclusions drawn from the diatom data. In addition, the use of multiple indicators also allows questions of ecological response to environmental forcing to be addressed using diatoms. Perhaps in the future, our research should focus more on using fossil diatom compositions as response variables and early warning indicators rather than using them to reconstruct environmental change *per se*. For this, however, a more comprehensive understanding of the role of diatoms in the functioning of aquatic ecosystems is required.

Diatomites: Their Formation, Distribution, and Uses

R J Flower, University College London, London, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Diatoms are ubiquitous microalgae; they grow in both terrestrial and aquatic habitats and occur in most regions of the world. Because these algae possess resistant siliceous cell walls, their remains are often preserved in sedimentary environments and, where they are sufficiently abundant, diatomaceous deposits can accumulate. Such deposits are composed predominantly of diatom valves or frustules and are collectively referred to as diatomite. Diatomites vary considerably in texture and composition and are known by a variety of names, including kieselguhr, diatomaceous earth, fuller's earth (bentonite), and tripolite. Despite differences in precise composition that are attributable in part to the nature of the diatoms preserved (diatom valves can vary from about 5 to 200 μm in diameter), the word diatomite is generally used to describe any sedimentary deposit where the proportion of diatom remains or of diatom silica is high. When extracted, diatomite can contain a considerable proportion of water as well as non-biogenic clastics and organic material. The term diatomite is often used for sediment where silica exceeds 50% of the bulk sediment, and commercially useful diatomite contains more than 80% silica (e.g., Kadey, 1983). Diatomite deposits have a worldwide distribution and can be either freshwater or marine in origin, ancient or modern, and can usually be readily identified in the field as gray sediment (friable when dry) with a low specific density. In this article, the formation, preservation, distribution, and uses of diatomite are considered.

Diatomite Formation

Whether in past or contemporary environments, the process of diatomite formation is essentially the same: prolific diatom growth in either fresh water or seawater and the subsequent accumulation of their siliceous remains into a sedimentary deposit. Key aspects of diatomite formation are high diatom productivity supported by adequate light and dissolved nutrient availability (especially of dissolved silica), good diatom preservation (see Section 'Preservation of Diatoms'), and perhaps most importantly, the lack of any significant terrigenous, or other biogenic or clastic materials diluting the diatom component of the accumulating sediment (Harwood, 1999). Terrestrial diatomites are all fossil deposits and enjoy a worldwide distribution; both freshwater and marine fossil diatom deposits are common.

The formation of diatom-rich deposits is indicated schematically in Figure 1. The figure indicates two extreme processes for diatom deposition. On the left of Figure 1, the basic mode of diatomaceous sediment formation in a deep water environment is indicated. Here, diatom phytoplankton grows in the illuminated upper part of the water column. As the crop develops, diatoms begin to sink and mass sinking events mark the culmination of growth periods as the diatom

phytoplankton bloom collapses. Following a period of sinking (which depends on water depth), the dead and senescent diatoms are deposited onto the ocean floor or lake bed. Once deposited on the surface sediment, the diatoms are subjected to taphonomic processes (see below) as they are incorporated into the permanent sediment record. In shallow water environments, diatomaceous sediments are formed rather differently. On the right of Figure 1, a shallow water environment is indicated and here diatoms grow within a short water column as well as in biofilms on subaqueous sediment and aquatic plant surfaces. Hence, the sinking depth is short or nonexistent, and diatom species are predominantly benthic or tychoplanktonic in habit, rather than planktonic. At the sediment surface, the diatoms are again subjected to taphonomic processes and, in some shallow water environments, these can be intensive, depending on the local environmental conditions. These shallow water deposits are normally formed only in freshwater habitats where the inclusion of aquatic animal and plant macrofossils (such as fish and charophyte remains) often confirm the shallow water depth of the system.

In an oceanic environment, diatom-rich sediments are referred to as diatom oozes and they occupy significant areas of the world's ocean surface sediments, especially in the Southern Hemisphere. These oozes occur most extensively in cold water regions, notably around the productive Antarctic convergence zone but also in the central eastern Pacific where high diatom productivity is supported by nutrient-rich upwelling currents. These pelagic sediments are composed of at least 30% biogenic silica and the diatoms are nearly all planktonic. In deep freshwater lakes, the formation of diatomaceous sediment is somewhat similar to that observed in the oceans; for instance, diatom ooze accumulates in Lake Baikal, Siberia. This is especially so for the north basin of this great lake. In shallow lakes, benthic diatom production requires that the sediment surface lies within the photic zone and that the diatoms are growing in fairly clear water with only small amounts of terrigenous material entering the system. Interestingly, many shallow freshwater diatom deposits are closely associated with geologies that potentially supply abundant dissolved silica for diatom growth. Hence, locations where these diatomites have formed are often associated with characteristic geological formations (basalts, tephra, and volcanic deposits) that are rich in silica. Such associations are found in locations as disparate as Lillcur (Australia), Lomocastro (Costa Rica), Leizhou (China), and Toome Bridge (Northern Ireland).

Irrespective of whether a freshwater or marine environment is considered, diatoms deposited onto or growing on a subaqueous sediment surface are subjected to a variety of sedimentary processes. Those that affect diatom fossilization are referred to as taphonomic processes. These include sediment disturbances of various kinds (sediment resuspension and bioturbation, sediment dewatering) that can break or dissolve at least some of the deposited diatoms. Surface-sediment

Figure 1 Formation of diatomaceous sediments. Left indicates the processes involved in the formation of diatomaceous sediment in a deep water environment. Right indicates the processes involved in the formation of diatomaceous sediment in a shallow water environment. The essential difference between these environments is light availability; in shallow water, light promotes growth of both benthic (as a biofilm on surfaces) and planktonic (free-floating) diatoms, but in deep water, diatom plankton growth is restricted to the upper illuminated surface water. Closed arrows indicate water circulation and open arrows indicate sinking diatoms.

taphonomic processes can operate until permanent burial; then slower sedimentary processes (compaction and diagenesis) take over and transform the diatomaceous sediment into diatomite. Most importantly for diatomite formation, the overall sedimentary environment must be conducive to the preservation of diatoms. However, after incorporation into permanent sediments, diatom remains can persist for millions of years.

Preservation of Diatoms

Diatoms are prone to damage and dissolution and these processes can combine to diminish the quantity and quality of diatoms accumulating in sediments. Most processes inimical to the preservation of a high portion of sedimentary diatom remains operate within the water column or at the mud water interface on the sea or lake floor. Diatoms will tend to dissolve whenever the surrounding water is undersaturated with regard to dissolved silica (e.g., Shemesh et al., 1989), and preservation will be further reduced by breakage, often encountered in high-energy environments and promoted by grazing (cf. Flower, 1993). Depending on water column depth, the degree of silicification of individual species of diatom, and a variety of water quality characteristics, diatoms will be preferentially preserved, but major initial losses by dissolution can occur, even in areas with sediments rich in diatoms. In Lake Baikal, for example, over 99% of diatoms produced in the euphotic zone dissolve before being incorporated into sediments. Some dissolution occurs in the water column, but most of it occurs as a result of surface-sediment processes (Ryves et al., 2003). Diatom remains in diatomites can show a range of preservational states from good to very poor and, although dissolution and breakage occurs to various extents during sediment formation, the

preservational condition of some terrestrial diatomites decreases from aerial exposure and weathering.

Over geological time, diatom silica changes state; the physical frustular structures disappear as the initial opaline silica of the diatom cell wall loses water and changes state, eventually becoming chrysotbolite. Despite differing formation processes, we can generalize that diatomites form in shallow or deep water environments as a result of moderate to high diatom productivity, adequate preservation and an absence of diluting detrital materials. Because of the instability of opaline silica, diatomite deposits are indicative of the most recent geological period, the Cenozoic.

Diatomite Distributions and Age

Terrestrial diatomite deposits occur on all the major continental land masses and, although Quaternary deposits are most frequent, many date from the Miocene Period. The Pre-Quaternary deposits are often substantial, usually marine in origin, and are particularly frequent around the margins of the Pacific Ocean (Reading, 1978). A well-known example is the extensive Miocene Monterey Formation in California, but other similar examples exist in Japan, South Korea, Eastern Russia, and in South America. Although the Monterey formation is large and variable, the Toro Road exposure (Barron, 1976) consists of almost pure marine diatoms, but preservation is often poor with many valves being broken. Aquitanian-Burdigalian and Messinian diatomites occur in countries bordering the Mediterranean, and Reading (1978) lists Romania, Spain, Sicily, Algeria, and northern Italy as regions with abundant marine Miocene diatomite deposits. The Miocene seems to have been a time of particularly extensive diatomite formation and the world's largest (marine) diatomite deposit of this period is probably at Lompoc in California (Dolley, 2002). Reading (1978) attributes the prevalence of Miocene diatomites to both tectonic and global climatic changes but Kidder and Gierlowski-Kordesh (2005) suggested that the nonmarine Miocene diatomite deposits are associated with the rise of grasslands and changes in the silica cycle. However, increased widespread weathering of silica-rich source rocks such as basalt may be a more likely source of dissolved silica at that time.

Freshwater diatomites are common around the Tertiary/Quaternary boundary and those dating across the Plio-Pleistocene periods occur in sections often tens of meters thick at several locations around the world. Notably, such freshwater deposits occur in Central (Mathers et al., 1991) and North America (Bradbury and Krebs, 1982), China (Qu and Chen, 2005), and Africa (Gasse, 1980). See Trauth et al. (2005) for a summary of diatomite sequences in East Africa. One Quaternary diatomite exposure (Figure 2) in central Kenya is over 30 m deep; it is near ancient Lake Kariandisi and has been dated to 0.97–0.974 Ma (Trauth et al., 2005). Its existence illustrates the development of wet periods in the East African Rift Valley zone at that time (M. Maslin pers. comm.). Also in Africa, extensive diatomite deposits occur around the Lake Chad area and these extend into the Holocene epoch. Diatomite samples collected as part of the 'ACACIA' (Arid Climate, Adaptation, and Cultural Innovation in Africa) Project from the former Lake Megachad and elsewhere in this

Figure 2 Exposed outcrop of freshwater diatomite from ancient Lake Kariandusi in Kenya. The section dates to 0.97–0.974 Ma and illustrates a former wet period in the East African Rift Valley system (see Trauth et al., 2005). Note that several caves have been excavated in the basal diatomite section. Photograph by M. Maslin.

region contain abundant freshwater plankton such as *Aulacoseira granulata*, *Cyclotella* (= *Discostella*) *stelligera*, and *C. ocellata* and benthic diatoms (especially *Cocconeis placentula*, *Denticula*, and *Epithemia*), as well as tephra deposits (Gasse, 2002; D. Verschuren, pers. comm.). These diatom species indicate the former presence of clear dilute alkaline water of varying water depths. The Bodélé depression (northern Chad) contains large areas of exposed diatomite, which are a globally significant source of wind-blown dust (Giles, 2005).

Another region with extensive Pliocene–Pleistocene diatomites is Central America. Deposits of freshwater (mainly planktonic) diatoms in Costa Rica can reach 100 m in thickness (Mathers et al., 1991). These also often contain abundant macrofossils of fish and other aquatic organisms. Other very extensive diatomite deposits occur in the Far East, particularly China, where they are often associated with volcanic formations and tephra deposits. In China, they typically date from the Pliocene to Holocene (Shang, 2003). The commercial diatomite deposit in the Leizhou Peninsula (North China) is reported to be of middle Pleistocene age (Qu and Chen, 2005) as are those in southwestern China, especially in Yunnan Province (Shang, 2003).

Holocene freshwater diatom deposits occur globally, but they tend to be thin, often being only several meters or less thick, and are often localized in distribution. Only a few lakes seem to be accumulating diatomite-quality sediment today. Lake Myvatn in Iceland is one lake where diatomaceous sediment is accumulating and where diatomite was being extracted commercially until recently (Kjaran et al., 2004). Many recent diatomite deposits, however, seem to have formed during the early to mid-Holocene. They are regional in distribution but very widespread; Eardley-Wilmot (1928) gives a thorough account and maps such deposits in Canada (notably in British Columbia and Nova Scotia). In the United Kingdom, Holocene diatomites occur at sites such as Toome Bridge in Northern Ireland (Wilson, 1972), in Loch Cuithir and other basins on the Isle of Skye in Scotland (Robertson, 1945), and

Figure 3 The exposed and wind-eroded surface of a Holocene freshwater diatomite deposit near Lake Qarun (Egypt). Note that the desiccation fissures in the exposed diatomite surface are filled with wind-blown sand. Photograph by R.J. Flower.

in England, notably at Kentmere (e.g., Round, 1957). Today, human activities have accelerated soil erosion and promoted cultural eutrophication of inland water bodies, all processes that tend to diminish the proportion of diatoms in accumulating sediments.

One rather local but environmentally significant Holocene diatomite deposit occurs in the Faiyum Depression (Egypt) to the north and southwest of modern Lake Qarun (Flower et al., 2006). This material was explored by Aleem (1958); it occurs as large expanses of white sediment, several meters thick in places, and is interspersed with blown sands (Figure 3). Fish remains are abundant and according to Wendorf and Schild (1976) these calcareous diatomites were deposited in several stages when the present lake was much larger. However, dates are few and not directly made on the diatomite, but on organic matter within diatomite sections. Radiocarbon dates indicate the deposit is of early Holocene age, with some sections younger than 5550 years BP. Other diatomite deposits occur around the northern fringes of the Sahara and especially in Algeria (Baudrimont, 1973), and some date to the Neolithic period. Collectively, they indicate a freshwater crisis during the middle Holocene as climate change and aridity affected much of Northern Africa.

The Use of Diatomites

Diatomites have two principal uses, one is commercial and entails extraction and processing into various diatomite products and the other relates to their value as an archive of past environments and of environmental change. Regarding the former, diatomites have been used by people for several thousands of years, but it is only during the last 200 years that diatomite deposits have been extracted on a commercial scale.

Diatomite Extraction

Use of diatomite materials first requires extraction of a suitable deposit, followed by fabrication into materials appropriate for distribution. Whether one considers ancient or modern uses,

the activities involved are similar and entail both extraction and processing. The ancient methods seemed to have focused on cutting blocks of diatomite sediment or manufacturing diatomaceous mud bricks. For the latter, diatomites were mixed (presumably by hand) with water and plant materials (usually straw), molded, and dried in the sun (Flower, 2006; Spencer, 1979). More recently, traditional diatomite extraction in the United Kingdom was largely done by hand and the techniques depicted by Wilson (1972) for diatomite products from the Toome Bridge area of Northern Ireland are typical. Diatomite bricks were cut by hand, stacked into piles for air drying and then milled to produce a fine dry powder product for bagging and sale. A commercial company (W. Kenyon Ltd.) exploited these deposits from around the outflow of Lough Neagh until recently and the remaining deposits are now protected under environmental legislation. Small-scale diatomite extraction was also formerly undertaken in Scotland, especially on Skye where eight diatomite sites occur in the Trotternish area. The Loch Cuithir site was worked on until 1914 and again after 1937 (<http://canmore.rachms.gov.uk/en/1131/>). Nevertheless, during the 1950s and 1980s, commercial extraction of diatomite effectively ceased in the United Kingdom, even though the feasibility of small operations is still debated. Elsewhere in the world, diatomite extraction is currently big business, and this is particularly so in the United States, China, and the former Soviet Union countries, where advanced plant machinery and high-temperature drying of the product are deployed. Other countries with commercially active diatomite extraction industries include Australia, Denmark, Spain, and countries in South and Central America (see Dolley, 2002; Eardley-Wilmot, 1928). World production of diatomite averaged about 1.65 million tons per year from 1988 to 1992 (British Geological Survey, 1992).

Ancient Uses of Diatomites

Archaeology has indicated some interesting applications of diatom-rich materials but the extent of their use is unclear. Nevertheless, the value of diatomite as a lightweight, easily handled material seems to have attracted interest. Dolley (2002) noted that lightweight building bricks of diatomite were used by the ancient Greeks and that diatomite blocks were used in the construction of the sixth century Hagia Sophia church, Istanbul. In ancient Egypt, the Ptolemaic inhabitants of the archaeological site of Dimai in the Faiyum also seemed well aware of at least some of the properties of diatomite deposits. Mud bricks at Dimai were fabricated from local diatomite deposits and used in the construction of dwellings, a funerary complex, and official buildings (Flower, 2006). Diatomite can be found frequently exposed near Dimai (Figure 4) but whether this material was actively sought for making mud bricks is unknown. It is thought, however, that the insulating properties of diatomite could well have helped to keep buildings internally cool in the hot climate. Diatoms in building materials are known in archaeological sites elsewhere, but they seem to be present as passive tracers of source materials. Caton-Thompson and Gardner (1934) described a region, also near Dimai, of siliceous (diatomite) deposits that were irrigated and used as a soil base for crop cultivation in Ptolemaic times.

Diatomites in Modern Commercial Usage

It is the basic structure of diatomite, its high porosity, large surface area, abrasive quality, insulation capability, and refractory nature that makes it so useful commercially. The principal commercial uses of processed diatomite are in the food and building industries but it also has applications in the chemical, agricultural, and related industries (Eardley-Wilmot, 1928).

In the food industry, diatomite-derived products (usually powders) are useful as a filtrant or as an absorbent for liquids produced for consumption. There are a variety of liquid clarification aids produced commercially and these are all designed to remove impurities and to clarify liquids. Hence, wine and beers are often treated and clarified with processed diatomite as are certain oils and fats. In the chemical industry, diatomite products are used as filler and as a valuable additive to many paints, rubber, and plastics. Diatomite particles are an effective absorption medium for some macromolecules and can be used to selectively capture some dissolved organic compounds. Because of the mildly abrasive nature of diatomite, it is also used in the manufacture of polishes and in some toothpastes. In agriculture, processed diatomite has several uses as a soil additive; it improves soil quality (mainly through its ability to take up and retain water) and it can act as a snail and slug repellent or to protect stored grain from insect pest attack (Arnaud et al., 2005). In some agricultural locations, natural surface soil consists largely of diatomite and the resulting light and freely draining soils are favored in Northern Ireland for growing root crops (Cruickshank, 1982).

Some twentieth century uses of diatomite are being replaced by modern synthetic materials, but it is in the building industry that diatomite retains considerable potential. Traditionally, diatomite has been the material of choice in the manufacture of fire bricks, where the fine-grained siliceous material confers high insulation value. A range of brick and tile diatomite products have been developed with varying degrees of success (Eardley-Wilmot, 1928). However, more recent research on the addition of diatomite products to building materials, cements, and building bricks, has shown

that the structural properties of these materials can be improved. Addition of diatomite to fabrication processes of modern building bricks can influence the pozzolanic properties of the product (Wild et al., 1997). The pozzolanic properties of high-reactivity silica in diatomite produce cements with increased strength and compressibility resistance, and their benefits are similarly useful for ceramics. The properties of various diatomites are being tested as an additive in modern light weight building bricks where strength and insulation are needed (Pimraksa and Chindapsirt, 2009). The reaction of the silica surfaces in diatomite with aromatic compounds is the focus of interesting new research and Goa et al. (2005) showed that surface-modified diatomite can be a very effective trap for aqueous phenol. Hence, treated diatomite could have potential applications for combating water pollution.

Diatomites in Environmental Science

Diatom-rich sediment sections in marine diatom deposits have long been used for exploring paleodiversity in diatoms. Well-known sites are in New Zealand (the Oamaru Deposit, Grove and Sturt, 1853) and in California (the Moreno Shales, Hanna, 1927). Later, diatom-rich marine sediment cores were examined to demark biostratigraphic facies, to help define correlations and sedimentary chronozones, and to demonstrate species evolution (e.g., Strelikova, 1990). Similarly, terrestrial deposits of freshwater diatoms have been evaluated since the mid-nineteenth century. These were examined initially from the point of view of diatom diversity, and it was not until the 1980s that these deposits were used to develop a worldwide lacustrine chronobiostratigraphy and to infer climate change. Bradbury and Krebs (1982) studied Miocene to Holocene diatomites in Idaho and Oregon and indicated that at least seven taxa were identified as being common to lacustrine deposits at various locations in the Northern Hemisphere. Working in Ethiopia, Gasse (1980) used the diatom stratigraphy of a 31-m section of diatomite to show that the diatom record was indicative of past environments where water quality and climate fluctuated.

On a more recent time scale, diatomite has also been employed as a tracer in freshwater systems (e.g., Lund, 1974) and as a stratigraphic marker to estimate sediment accumulation in both lakes and salt marshes. Diatomites have also been examined to reveal species changes according to past lake-level variations and, normally being terrestrial deposits, they can be readily sampled at exposures or cored with hand-operated equipment (Figure 5). Holocene diatomites near extant lakes such as Lough Neagh in Northern Ireland (Plunket et al., 2004) and Lake Qarun in Egypt (Wendorf and Schild, 1976) have been used to document lake-level fluctuations in relation to the establishment of early human occupation sites.

Conclusions

Diatomites around the world have provided people with a rich source of material for both commercial exploitation and paleoenvironmental science. Commercial uses of diatomite are changing, and some applications are diminishing due to

Figure 5 Sampling a Holocene freshwater diatomite deposit in the Toome Bridge area of Northern Ireland. Note the exposed cut face of the diatomite deposit in the foreground and the upper 20–30 cm of soil cover. The semi water-logged deposit is about 1.5-m thick and a Hiller corer is being used to collect a stratigraphically ordered sequence of samples for paleoenvironmental analysis. Photograph by R.J. Flower.

the development of cheaper alternatives. Yet diatomite has considerable potential as an additive to building materials and it also has promising applications in the organic chemistry industry. As for paleoenvironmental research, there are rich opportunities for further exploitation of the biostratigraphies of diatomite deposits as recorders of past climates, human–aquatic ecosystem interactions, and of diatom species evolution.

Acknowledgments

The advice and analysis provided by colleagues in the Department of Geography, especially N. Cameron, V. Jones, H. Yang, and M. Maslin, are gratefully acknowledged. M. Hamdan, G. Tassie, and M. Hughes contributed to the field work depicted in Figures 2–4. M. Irving kindly provided the artwork. The work was partly funded by the Leverhulme Trust and the British Academy (UK).

Salinity and Climate Reconstructions from Continental Lakes

S C Fritz, University of Nebraska – Lincoln, Lincoln, NE, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

Diatoms are widely used to reconstruct past environments because of their sensitivity to a range of environmental variables (see [Diatom Introduction](#)). Among the variables that exert a strong influence on diatoms are ionic concentration, expressed as salinity or conductivity, and ionic composition. Because the ionic concentration and composition of inland water bodies is affected by changes in effective moisture (precipitation minus evaporation, $P-E$), changes in the abundance of diatom species that vary in their salinity tolerances provide a tool for the reconstruction of past climate.

The use of diatoms to infer changes in salinity driven by climate relies on settings where effective moisture variation is moderate to large and produces relatively large changes in lake salinity. These conditions are most common in semiarid and arid regions, where evaporative forcing is strong, and in topographically closed lakes where changes in $P-E$ have the potential to concentrate or dilute dissolved salts. These conditions are widespread in the dry interiors of continents, in subtropical deserts, and in dry polar regions. Thus, diatom-inferred salinity can be used to reconstruct effective moisture from lake deposits in many regions of the globe.

In practice, the inference of climate from diatom-inferred salinity is complicated by the diverse controls on the hydrologic budgets of lakes and, occasionally, the accurate inference of salinity from diatoms may be obscured by other ecological influences. Nonetheless, diatom records have played a critical role in developing the understanding of the extent to which twentieth-century climate patterns are representative of long-term climate variation and of the patterns and controls on climate variability at decadal to orbital time scales.

Diatoms as Indicators of Salinity and Ion Composition

Salinity Classification of Diatoms

Diatoms have long been recognized as indicators of ionic concentration (salinity). [Kolbe \(1927\)](#), and subsequently [Hustedt \(1953\)](#), developed a system to classify diatoms according to their distribution in waters of varied salinity, the so-called halobion system. This system was primarily based on distributional patterns in sodium chloride (NaCl)-dominated marine and coastal environments, from marshes and estuaries receiving fresh surface runoff to the open ocean where salinity reaches $\sim 35 \text{ g l}^{-1}$. Although this halobion classification was applied to lacustrine diatoms in the mid-1900s, it is not well suited for diatoms in continental lakes because of the much broader range of salinity and ion composition found there.

Studies to characterize the salinity ranges of lacustrine diatoms expanded in the 1970s and 1980s, when the potential to reconstruct past climate change from lake sediments became more broadly recognized ([Ehrlich, 1978](#); [Gasse, 1977](#)). During the last few decades, studies of the distribution of diatoms

relative to gradients of salinity and ion composition have been carried out on all the continents and in lakes from the high latitudes to the tropics and have fueled the use of diatoms as paleoclimatic indicators.

Diatoms occur in the full range of lakes from dilute freshwater to hypersaline brines ([Figure 1](#)), and classification schemes reflect this diversity of environments. One of the most commonly applied classification systems splits lakes and their associated diatom floras into freshwater ($<0.5 \text{ g l}^{-1}$), subsaline ($0.5\text{--}3.0 \text{ g l}^{-1}$), hyposaline ($3.0\text{--}20 \text{ g l}^{-1}$), mesosaline ($20\text{--}50 \text{ g l}^{-1}$), and hypersaline ($>50 \text{ g l}^{-1}$) waters. Many species have distributional limits near the overlap of the subsaline and hyposaline ranges, and the diversity of taxa is low in mesosaline and hypersaline systems ([Fritz et al., 2010b](#)).

Although the distribution patterns of many diatoms are correlated with salinity, the mechanisms for this correlation are not well understood. Salinity imposes an osmotic gradient and hence an energetic cost on cells. At high salinity, diatoms manufacture proline or other osmolytes to deal with the osmotic gradient; many of these compounds are amino acids and rich in nitrogen. Thus, under high salinity, nutrient requirements may be higher ([Saros and Fritz, 2000](#)). Other compounds that are correlated with salinity gradients also may affect nutrient uptake by diatoms. For example, high concentrations of sulfate may interfere with molybdate uptake, a critical component of enzymes involved in nitrogen utilization. Many saline lakes in grasslands also have high dissolved organic carbon concentrations (DOC) and low chlorophyll relative to ambient nutrient concentrations ([Salm et al., 2009](#)). This suggests that DOC may form complexes with a critical nutrient that controls primary production and thereby affects diatom productivity and species composition. Thus, several lines of evidence suggest that one of the major effects of changing salinity may be via its impact on nutrient availability, uptake, and requirements.

Diatoms also can be classified according to their distribution in waters of differing anion composition, and some species are characteristic of chloride, sulfate, or carbonate-bicarbonate-dominated waters ([Figure 2](#)). The reasons for differences in anion association also are unclear but are likely related partly to anion impacts on nutrient availability ([Saros and Fritz, 2000](#)). Shifts in anion composition of lacustrine systems can be indicative of changes in source waters, particularly groundwater, or of progressive changes in brine composition driven by climate.

Quantitative Approaches for Salinity Reconstruction

Since the mid-1980s, transfer functions applied to fossil diatom assemblages have increasingly been used in paleoenvironmental studies to quantitatively reconstruct salinity, conductivity, or some other environmental variable of interest. These transfer functions are based on modern calibration data sets, which sample a group of contemporary lakes that span a salinity

Figure 1 The salinity ranges (horizontal line) and salinity optima (dot) of selected diatom species from the Great Plains region of North America, generated from a survey of water chemistry and diatoms in the surface sediments of 66 regional lakes. Weighted averaging regression was used to calculate ranges and optima (see [Diatom Introduction](#)). Species are arranged from top to bottom in order of increasing salinity optima. Reproduced from Fritz SC, Juggins S, and Battarbee RW (1993) Diatom assemblages and ionic characterization of lakes in the northern Great Plains, N.A.: A tool for reconstructing past salinity and climate fluctuations. *Canadian Journal of Fisheries and Aquatic Sciences* 50: 1844–1856.

gradient and use these lakes to characterize the salinity range of diatom species (see [Diatom Introduction](#)) and the so-called salinity optimum, the salinity at which each diatom species is most abundant ([Figure 1](#)). A variety of statistical techniques can be used to generate transfer functions for the reconstruction of salinity or other environmental variables ([Birks, 2010](#)). The transfer function approach does not assume that salinity, or another reconstructed variable, is the proximate or physiological variable affecting diatom distribution, but simply that diatom distribution is highly correlated with salinity and that this relationship is stationary through time. In most cases, a regional transfer function cannot be independently tested by applying the function to a new group of lakes or by comparing a reconstruction from a sediment core with historic measurements of salinity from the same lake, although occasionally these sorts of data are available (e.g., [Fritz, 1990](#)). Therefore, statistical techniques for error estimation, such as bootstrapping or jack-knifing, are commonly used to evaluate transfer function performance ([Birks, 2010](#); [Fritz et al., 2010b](#)).

Figure 2 Diatom-inferred cation composition (x-axis) and anion composition (y-axis) inferred from a series of diatom samples from sediment cores from 12 African lakes. Sediment samples from each of the 12 lakes are represented by a different symbol. A weighted average calibration model developed from over 300 modern lakes in Africa was used to reconstruct cation and anion composition from these sediment samples (see [Diatom Introduction](#)). The groups A0, AI, AII represent different combinations of lake water cation and anion dominance, as indicated in the figure. Subgroups 1–4 represent progressively increasing salinity within a given group. Reproduced from Gasse F (2002) Diatom-inferred salinity and carbonate oxygen isotopes in Holocene waterbodies of the western Sahara and Sahel (Africa). *Quaternary Science Reviews* 21: 737–767.

Transfer functions for salinity reconstruction are effective in lakes that have undergone moderate to large fluctuations in salinity that exceed the standard error of prediction. Quantitative techniques also work best in systems where other water-chemistry variables that have a strong impact on diatoms, such as pH or nutrients, are less likely to show large changes over time. In theory, statistical approaches, such as variance partitioning, can account for the impact of multiple environmental influences on species distribution. In practice, however, modern data sets are constructed to optimize the environmental gradient of interest, in this case salinity, and other ecologically important variables may not be adequately accounted for. In these cases, the assumption that the relationship between species and salinity does not change with time may be invalid, such as has been demonstrated for diatom-based transfer functions for temperature ([Bigler et al., 2002](#)). Because of these issues, salinity reconstructions are most robust when they are corroborated by inferences from other proxies, such as ostracodes, chironomids, sedimentology, or sediment geochemistry ([Aebly and Fritz, 2009](#); [Gasse, 2002](#); [Kropelin et al., 2008](#)).

Quantitative reconstructions depend on having a modern calibration data set that accurately defines the environmental ranges and tolerances of diatom species. For most regions, the size of calibration data sets is less than 100 lakes, and although such a sample size can generate a statistically robust transfer function, it may not adequately capture the true optima of all taxa. In some regions, such as the tropical Andes, the density of modern samples is not yet sufficient to allow quantitative reconstructions, and the large number of apparently endemic species makes generalizations from the floras of other regions difficult. Finally, given the large range of environmental

change in the past, some regions may no longer contain aquatic environments that are modern analogs for past environmental conditions. Thus, in Africa and Mexico, some of the dominant diatom taxa in fossil records do not occur in the modern flora (Gasse, 2002; Metcalfe et al., 2002), even given large spatially distributed modern data sets.

Diatom Preservation in Saline Lakes

Although diatoms are a common component of the algal community in lakes from low to high salinity, they are not always well preserved in sedimentary records. Diatom dissolution is highest in sodium carbonate solutions, where high pH (>9) enhances the dissociation of silicic acid, but dissolution also occurs in other salt solutions (Barker et al., 1994). Brines can induce the formation of diagenetic silicates (e.g., zeolites and smectite), leading to alteration or dissolution of diatom assemblages. These processes can alter not only total diatom abundance in sediments, but also species composition because diatom species are differentially sensitive to dissolution and diagenesis (Barker et al., 1994; Ryves et al., 2001). In some cases, dissolution indices can be developed to correct for some of the bias imposed by taphonomic processes (Ryves et al., 2009).

Lakes, Salinity, and Climate

Climate affects the water budget of lakes via its influence on precipitation, surface evaporation, and groundwater flow. Shifts in a lake's water balance, in turn, alter lake salinity through concentration or dilution of ions in solution. The magnitude of the climatic imprint depends on the morphometry of the lake and its drainage basin; both lake surface area and volume, for example, affect the degree to which precipitation or evaporation influence lake level and lake salinity. Overall, the best candidates for climate reconstruction from diatom-inferred salinity techniques are subsaline to hyposaline lakes in semiarid to arid climates because variations in precipitation and evaporation cause salinity changes that are sufficiently large to produce shifts in diatom species composition. The rate of lake response to climate is a product of the lake's water residence time and the relative balance of surface flow relative to groundwater. In lakes where groundwater is a large component of the water budget, lake response is governed by the response time of the groundwater system, and short-term climatic change may have very little impact on the water and budget (Reed et al., 1999). Connection to a groundwater flow system also allows for loss of salts via subsurface outflow, whereas in a terminal basin (a basin without surface or subsurface outflow), salts build up over time.

Globally, subsaline and saline lakes outnumber freshwater lakes (Meybeck, 1995), and systems appropriate for paleoclimatic study are common in most of the regions of the world where water availability is limited. This includes the continental interiors of the Americas, Africa, Australia, and Eurasia, as well as the high-latitude regions of Antarctica and the Arctic. In the next section, examples of a range of lake systems are discussed in which diatom-inferred salinity has been used to infer paleoenvironmental and paleoclimatic history during the Quaternary.

Quaternary Environmental History as Inferred from Diatoms

Quaternary Climate Variation at Orbital and Millennial Time Scales

Shifts between freshwater and saline diatom taxa have been used effectively to infer moisture variation on orbital and millennial time scales in extant and former lake basins. In the Owens Lake basin in western North America (Bradbury, 1997), peaks in freshwater planktic diatoms and inferred deepwater conditions are broadly correlated with cold periods in the SPECMAP oxygen isotope record after ~400 000 years BP, when tectonic processes likely produced an increase in basin depth (Figure 3). Prior to that time, the evidence suggests that the basin was much shallower, and the correlation between intervals of increased planktic diatoms and cold climatic periods is not as strong. In Lake Titicaca in the tropical Andes, the increased abundance of freshwater planktic diatoms (Figure 4)

Figure 3 A comparison of the abundance of freshwater planktic diatoms in a drill core from Owens Lake, California compared with the SPECMAP $\delta^{18}\text{O}$ record of global temperature change – high isotopic values represent global cold periods, whereas depleted values are warm periods. The $\delta^{18}\text{O}$ record from a calcite vein at Devils Hole, Wyoming also provides a chronology of temperature change; in this case with more depleted (smaller) values representing colder periods. The relative proportion of diatoms in each sample was calculated using a standard sample count of 300 diatom valves. In a few samples with very high diatom concentrations, more than 300 valves were counted and thus percentages exceed 100%. Reproduced from Bradbury JP (1997) A diatom-based palaeohydrologic record of climate change for the past 800 k.y. from Owens Lake, California. *Geological Society of America, Special Paper* 317: 99–112.

Figure 4 The diatom stratigraphy of the last ~30 000 years from Lake Titicaca, Bolivia-Peru. The dominance of freshwater planktic diatoms is inferred to represent times when the lake was fresh and overflowing, whereas benthic (*Pseudostaurosira zelleri* and other taxa) and saline (*Chaetoceros muelleri*) diatoms dominate when the lake-level fell below the outlet threshold (see [Baker et al., 2001](#) for additional information).

indicates fresh overflowing conditions associated with increased precipitation, whereas benthic diatoms and the saline planktic taxon, *Chaetoceros muelleri*, indicate periods when lake-level fell below the outlet and salinity built up. In this case, the wet intervals are coincident with global cold periods, including the Last Glacial Maximum, when cold temperatures reduced evaporation and high summer insolation and cold Atlantic Ocean sea-surface temperatures (SSTs) enhanced the South American summer monsoon. During the contrasting conditions of global interglacial periods, lake-level declines of up to 240 m (modern water depth is 285 m) were sufficient to more than double lake water salinity ([Baker et al., 2001](#); [Fritz et al., 2007](#)); more discussion of the Lake Titicaca record is given in Mackay (this volume). Millennial-scale variations in lake level also are evident in Lake Titicaca and other lakes in the drainage basin and can be linked to climate variation in the North Atlantic region ([Ekdahl et al., 2008](#); [Fritz et al., 2010a](#)). In Africa, massive reductions in lake level are evident during the late Pleistocene in the diatom record from Lake Malawai, as well as in other proxies analyzed in the same core ([Stone et al., 2010](#)). Similarly, a 50 000-year diatom record from Tanzania shows the influence of global temperature change on regional hydrology ([Barker et al., 2003](#)). Here changes in lake level and lake conductivity show a strong relationship to SST change in the SW Indian Ocean ([Figure 5](#)), which forces changes in the position of the intertropical convergence zone (ITCZ) and hence influences precipitation in the African tropics.

Late-Glacial and Holocene Climate Change

Changes in salinity inferred from diatom records have played a prominent role in documenting hydrologic changes in the late-glacial period through the Holocene, particularly in

the Americas and Africa. In northern Mexico and the Great Basin of the southwestern United States, diatom records suggest that the late-glacial period was wet as a result of the southerly displacement of the westerly storm tracks, followed by drying in the early to mid-Holocene as the storm tracks moved northward ([Bradbury et al., 2001](#); [Metcalf et al., 2002](#)). In central Mexico, the opposite climate pattern is evident, with a dry late-glacial period because of a southward displacement of the ITCZ and a reduction in trade wind sources of moisture. Holocene salinity and moisture patterns across Mexico are spatially complex, as a result of the differential influence of rising sea level, dating uncertainties, and increasing human impact on the landscape in the late Holocene ([Metcalf et al., 2000](#)).

In Africa, diatom analysis has been instrumental in documenting massive precipitation changes during the late Quaternary, including the greening of the Sahara and Sahel in the early to middle Holocene ([Gasse, 2002](#)). At Bougdouma in Niger, for example, shifts between alkiliphilous benthic diatoms and freshwater planktic species suggest fluctuating water levels following the last period of glaciation ([Figure 6](#)). Stable wet conditions developed in the early Holocene (~10 300 years BP), followed by drying after 7300 years BP, a trend that is widespread throughout the Sahara and Sahel. Several wet pulses that produced a rising water table interrupted the drying trend, but conductivity and inferred aridity increased after 3800 years BP, with desiccation of the basin during the last 1000 years. These trends reflect variation in monsoon intensity across northwest Africa, but regional differences in the timing of lake salinity change reflect differences in the rate of response of different linked aquifer-lake systems.

The impacts of groundwater on lake response to climate have been highlighted in several paleolimnological studies. In some lakes of the Ethiopian Rift Valley, diatom-inferred water

Figure 5 The diatom stratigraphy of Lake Massoko, Tanzania compared with insolation and sea-surface temperature forcing. The detrended correspondence axis (DCA) scores summarize the patterns of change in the diatom species assemblage – samples with high DCA axis 1 scores are samples with high diatom-inferred conductivity and represent times of lowered P – E, an inference that is corroborated by pollen data. Reproduced from Barker P, Williamson D, Gasse F, and Gibert E (2003) Climatic and volcanic forcing revealed in a 50,000-year diatom record from Lake Massoko, Tanzania. *Quaternary Research* 60: 368–376.

chemistry does not show patterns of salinity change that would be predicted based on independent evidence for precipitation variation (Telford et al., 1999). For example, an interval of high diatom-inferred conductivity from Lake Awassa corresponds with strand lines in an adjacent basin that document a contemporaneous interval of high precipitation (Figure 7). Increased inputs of saline groundwater to one lake but not the other are the likely explanation. Similarly, a karst lake in the Konya Basin of Turkey showed little change in diatom-inferred conductivity during the late Pleistocene, probably because of relatively constant inflow of fresh groundwater, whereas a neighboring lake with limited groundwater flow showed evidence of changes in conductivity and lake level indicative of changes in effective moisture (Reed et al., 1999).

Complex salinity responses to climate change also are evident in intermittently meromictic lakes in West Greenland. Here, the amplitude of salinity variation is apparently affected by the stability of stratification, producing a nonlinear response of lake salinity to climate change (Aebly and Fritz, 2009; McGowan et al., 2003). In some intervals, increased diatom-inferred salinity correlates with evidence of increased precipitation from paleoshorelines. Complex groundwater interactions are unlikely in this region because of permafrost. In this setting, the observed response likely resulted from the coalescence of a freshwater lake with a lake of higher salinity

during times of increased precipitation or from the reworking of shoreline salt deposits as lake level rose.

The use of diatom-inferred salinity to infer changes in effective moisture also can be affected by the sensitivity of diatom assemblages to changes in salinity driven by climate. At high salinity, diatom diversity is commonly quite low, and the ecological tolerances of many high-salinity taxa are broad. Thus, species composition may not change as salinity changes. At Moon Lake, North Dakota, USA, for example, diatom-inferred salinity is very high during the mid-Holocene (Figure 8), indicative of the dry climate that was characteristic of the mid-latitudes of North America. But, the low variability in mid-Holocene diatom-inferred salinity probably results because changes in salinity caused by precipitation variation are not sufficiently large to change the composition of the diatom assemblage (Laird et al., 1996).

Diatom records from the North American Great Plains also provide an example of the use of diatom-inferred salinity to evaluate natural drought variation and the degree to which the twentieth century climate patterns are representative of the natural variability of climate. Records from a suite of lakes in the United States and the Canadian prairies clearly show that droughts equivalent in magnitude to the Dust Bowl droughts of the 1930s and 1940s were recurrent during the last millennium or two (Laird et al., 2003). These records also suggest that

Figure 6 The (a) diatom stratigraphy of Bougdouma in southern Niger and (b) various water-chemistry variables inferred from the diatom stratigraphy using transfer functions (lower figure). The cationic and anionic ratios are defined in Figure 2. The assemblages defined on the right-hand part of the figure (A0, AI, All) represent the inferred cation and anion water types as defined in Figure 2. Reproduced from Gasse F (2002) Diatom-inferred salinity and carbonate oxygen isotopes in Holocene waterbodies of the western Sahara and Sahel (Africa). *Quaternary Science Reviews* 21: 737–767.

drought was more prolonged in the recent past than during the twentieth century; some droughts apparently persisted for a century or more. One of the major difficulties with these high-resolution records, however, is in the correlation of the pattern of change among multiple sites; the errors associated with a radiocarbon chronology prohibit a clear correlation of changes at multidecadal scales. Even directional shifts that are persistent can be difficult to interpret in climatic terms. Thus, a major shift at the onset of Little Ice Age about 800 years BP is manifested as an increase in salinity at one site and a decrease at another nearby lake (Figure 9), and it is unclear whether the

differences reflect a sharp climatic gradient, or whether they are more likely due to differing hydrological responses to the same climatic forcing (Fritz et al., 2000).

Conclusions

The use of diatoms to infer past moisture variation in continental settings has increased greatly during the last two decades, and appropriate basins are widespread in semiarid and arid regions worldwide. In these regions, lacustrine records

often provide the best archives of long-term continental climate variation. Although some lakes in extremely dry climates may have discontinuous sedimentary records, in many basins, sedimentation rates are sufficiently rapid to allow the sedimentary record to be resolved at a subdecadal scale.

Although more studies are needed on how salinity and other ecologically important variables interact to influence diatoms, in many settings knowledge of diatom ecological tolerances is sufficient to enable robust reconstructions of qualitative changes in lake salinity. In some regions, calibration data sets have been developed to allow quantitative salinity reconstructions that are reasonably good at identifying the direction and relative magnitude of salinity change. In general, salinity change can be reconstructed from diatom assemblages with a high degree of confidence.

The inference of climate from salinity change is considerably more difficult, because of the potentially complex series of influences on the hydrologic budget of individual lakes. Although many of the issues involved in disentangling climate from biological and geochemical records are recognized (Fritz, 2008), more frequent application of modeling and empirical studies to quantify their potential impact in individual sites or regions would improve many paleolimnological interpretations. The tandem use of other proxies can help to constrain environmental interpretation from diatom records, although in some cases, reconciliation of apparently divergent inferences is not clear. Such cases also point to the need for more frequent integration of paleolimnology with modern process studies and modeling efforts. Overall the number of lacustrine records is still relatively limited, particularly at high temporal resolution and for periods much older than the Last Glacial Maximum. Thus, although the diatom paleoclimatology field has expanded in recent years, there is still a considerable distance to travel to unravel the patterns of environmental change across space and time, and the hierarchy of factors that produce them.

Introduction

Diatom analysis has been used in archaeological investigations for almost 60 years (for discussion and references see the review of [Battarbee, 1988](#)). Like other Quaternary paleoecological techniques, the results from off-site diatom paleoecological studies are often relevant to environmental archaeology. However, only diatom research that is integrated with field archaeology is considered relevant here. Specific collaboration between field archaeologists excavating ancient sites and archaeological sediments and diatomists interested in site environments and other aspects of archaeology has led to an increasing use of the technique in environmental archaeology. Unfortunately, the majority of published diatom-archaeological studies are of necessity placed in the appendices of archaeological site reports, making it difficult to gain an impression of the frequency with which the technique is applied in this context. However, diatom analysis is now more commonly known and used in archaeology, and often, particularly in the prehistoric context, it forms part of environment-led archaeological investigations ([Nayling and Caseldine, 1997](#)).

The applications of diatom analysis in archaeology have been reviewed by several authors ([Battarbee, 1988](#); [Juggins and Cameron, 2010](#); [Mannion, 1987](#); [Miller and Florin, 1989](#)). In this article, a number of case studies of on-site diatom-archaeological investigations are presented as examples.

Diatoms as Indicators of the Site Environment

As mentioned earlier, many diatom-paleoecological studies related to Holocene environmental reconstruction make a reference to catchment archaeology (human impact) as a factor in driving environmental change (e.g., [de Wolf and Cleveringa, 1996](#)) and indeed may discuss the archaeological or historical documentary evidence. Diatom environmental studies integrated with archaeological excavations are less common. An example of such a project is that of [Douglas et al. \(2004\)](#) who investigated the impact of prehistoric Inuit whalers upon Arctic freshwater ecosystems. Despite their low population densities and the nomadic nature of Inuit whalers, it was shown through a combination of archaeological and paleolimnological data that human settlement markedly changed pond water ecology from an early date. Winter settlements were constructed from the bones of bowhead whales on Somerset Island in the high Canadian Arctic between about 1200 and 1600. Archaeological excavation, recovery of artifacts, and radiocarbon dating document this occupation and allow for estimation of the population size. Diatom analysis ([Figure 1](#)) indirectly records marked changes in water chemistry and diatom habitat. Although the whalers abandoned the area over 400 years ago, the pond today retains elevated nutrient concentrations and biota atypical of the region.

In diatom-based studies of Danish lakes, [Bradshaw et al. \(2006\)](#) have shown that in the Bronze Age and Iron Age there was moderate eutrophication. Large increases in nutrient levels accompanied changes in agriculture and the retting of hemp and flax in the Medieval period. These studies demonstrate that human activities in lake catchments had a long-term (millennial) impact and that significant eutrophication is not restricted to the modern period (post-1800).

It is more common to find diatom analysis used in archaeological studies from urban contexts in towns in Europe. An example of this kind of analysis is work carried out by [Demiddele and Erynck \(1993\)](#) using diatoms as ecological indicators in an excavation of Roman and Medieval Oudenberg in the west of Flanders. During the Roman period, waterlain sediments in the town showed a high proportion of marine species reaching the town through tidal creeks. However, during the Medieval period, freshwater and low salinity species dominated the assemblages, indicating the disappearance of a marine influence with implications for water transport to the town. In addition, the diatoms from the medieval contexts corroborate evidence from other sources that there was heavy organic pollution of the water courses. Diatom analysis was therefore of relevance here, both in looking at the influence of tidal waters on human activities and on considering the impact of humans on site water quality. Diatoms have also been used for archaeological environmental reconstruction over larger areas in landscape archaeology projects. This is exemplified by work carried out over several seasons of excavations on wetlands bordering the Severn Estuary, UK, where diatom analysis supported evidence for large-scale Roman land reclamation ([Rippon, 2000](#)).

Diatom Analysis of Artifacts and Ancient Building Materials

Diatom analysis has been used in the direct study of artifacts, particularly in the investigation of pottery clay provenance and pottery typology, and also in identifying the sources of materials and the manufacturing techniques used in ancient buildings.

Where the firing temperature is low enough to allow the survival of diatom valves, diatom analysis of pottery can assist in the identification of clay sources or in the understanding of the provenance of finished pottery. Where adequate diatom assemblages are preserved, diatom assemblages can also be used to assist in the establishment of typologies for pottery or in the comparison of typologies with pottery style-based classification schemes ([Alhonen et al., 1980](#)). In addition to diatoms derived directly from clay, the mixture of diatoms derived from tempering materials and from water used in the manufacturing process can form part of the species assemblage. The use of diatoms in the analysis of pottery, which,

Figure 1 Diatom analysis of lake sediments from the Canadian Arctic showing the impact of Inuit whalers on water chemistry and diatom habitat. because of the requirement for a low-temperature firing, is usually of prehistoric age, has been reviewed by Battarbee (1988) and by Juggins and Cameron (2010). Stilborg et al. (1997) published a microfossil analysis of late Roman Iron Age pottery (AD 200–400) from a region of present-day Denmark. Just the presence or absence of siliceous and calcareous microfossils was used to group and separate pottery sherds. Two groups were established and the diatomaceous class, known as ‘D-ware,’ was further subdivided into sherds containing exclusively nonmarine diatoms and a subgroup containing a mixture of marine and nonmarine species. From this classification, it was also possible to infer the clay sources used for the pottery. In some of the classes of pottery, it was established that a mixture of clays was used during manufacture.

In a similar way, diatom analysis has been used to examine ancient building materials (Flower, 2006). Flower examined the diatom content of ancient mud bricks. These were used in ancient Egypt from approximately 5000 BP (Figure 2) and such bricks continue to be made in this way in the region today. The bricks are made from a mixture of mud, sand, water, and plant material. Diatom analysis of the bricks thus offers the possibility of investigating the provenance and uses of these building materials. Analysis of diatoms from a mud brick from a temple at Dimai showed that the diatom ‘mud’ component was almost certainly extracted from somewhere nearby, now terrestrial, diatomite that had accumulated in a former large lake. In contrast, the few, predominantly planktonic diatoms found in brick from a 12th Dynasty Pyramid at Hawara were thought to have been introduced from Nile water during manufacture. Flower notes that his results are preliminary, being based on a small number of samples. However, he

Figure 2 Buildings at the Ptolemaic Temple at Dimai, Egypt, dating and showing mud brick construction. Photograph taken by Dr. Roger Flower.

demonstrates that diatoms in ancient Egyptian mud bricks (and potentially other mud bricks) can provide important clues to the selection of raw materials, the manufacturing processes and the past environments associated with the raw materials. Flower observes that it is unclear whether ancient Egyptian builders exercised any preference for diatom-rich sources for their bricks. However, the well known insulating properties of diatomite would be advantageous in the construction of buildings. He emphasizes that diatom analysis of ancient building materials is also potentially useful not only for mud brick typification but also for making space-time correlations between mud brick facies, within and between monuments.

Salt Extraction Sites

Salterns are sites where salt is produced by the evaporation of salt water in shallow pools, and sometimes with the aid of hearths. In Europe, from the Iron Age through to Medieval times, such sites were found near salt water in places such as estuaries and salt marshes and also near inland sources of mineral salt. As a result of their sensitivity to salinity, diatoms have been used to assist in the environmental analysis of such sites and in the identification of the functions of specific areas of such sites (e.g., Juggins, 1992).

Moats and Medieval Fish Ponds

Man-made water bodies such as moats and fish ponds dating from Roman to Medieval times are associated with sites such as settlements, villas or farmhouses, fortifications, and monastic sites and can provide local and, sometimes, well-dated diatom-based environmental evidence for the effects of human activities. An example of this is provided by diatom analysis carried out in association with the archaeological excavations at the Tower of London Moat (Keevill, 2004). At the Tower of London a number of sources were found to influence water quality over a 600-year period from 1240 to 1843. The input of estuarine water from the tidal River Thames was evaluated using ecological groups of diatom-salinity preferences. Saline water entered this moat through the Traitor's Gate and the input varied through time. Although there was little archaeological evidence for the dumping of refuse directly into the moat, organic pollution was derived from drainage from the Tower, and also from waste disposal into a water course, the City Ditch, which drained from the external City settlement into the Moat. Using a diatom-phosphorus transfer function, total phosphorus (TP) levels indicated nutrient enrichment (Figure 3) in excess of that found at pre-Medieval sites elsewhere in London that have been analyzed for diatoms. Diatom analysis has been used in a similar context to examine sediments from two profiles taken from a ditch draining the moat surrounding fortifications in Prague, initiated in AD 1230 (Beneš et al., 2002). Here the diatom analyses revealed that a relatively clean, fast-flowing stream tended to flush organic pollutants quickly away from the urban environment. Only toward the end of its function as a gutter, when the feature became clogged with sediment, did slowing of the current lead to stagnation. Even then the degree of nutrient enrichment

Figure 3 Section through Medieval sediments from the Tower of London moat, showing variation in the diatom-based TP reconstruction. Reproduced from Keevill G (2004) *The Tower of London Moat. Archaeological Excavations 1995–9*, pp. 315. Historic Royal Palaces Monograph No. 1. Oxford: Oxford Archaeology with Historic Royal Palaces. Copyright N. G. Cameron.

remained surprisingly low, with water quality comparable to 'recreational water supply' according to present-day norms. Diatom analysis of sediments from a ditch and moat-like feature from the Castle of Kastelholm, Åland, Finland was also used by Nunez and Paabo (1990) to ascertain whether these features were connected with the sea. The presence of coastal diatom species in the samples seemed to confirm that this was the case; however, as is common with archaeological sediments, the low concentration and fragmentary state of the diatoms from the ditch suggested that in this feature they represented secondary deposition from the ditch bank when the castle island was below sea level. Like many archaeological contexts, the interpretation of the diatoms at this site was therefore based on the state of diatom preservation in addition to the diatom composition. In much of the routine environmental archaeology evaluation work carried out in the United Kingdom, for example, the aims of a diatom assessment are to determine if diatoms are present and to assess the potential for possible percentage analysis of the diatom assemblages and its value. Before more detailed analyses are considered, sample characteristics examined include diatom valve concentrations, the quality of diatom preservation (the degree of breakage and dissolution), and the diversity of taxa, as well as the types of diatom assemblage and the environmental preferences of the diatoms present.

Crannogs

Crannogs are man-made islands constructed in lakes and in sea lochs that support buildings. These structures are found in northern and northwestern Europe and date from the Bronze

Age to late Medieval times. Diatom analysis has been used as part of a multiproxy investigation of a crannog in a lough in central Ireland (O'Brien et al., 2005). Here the crannog was constructed in the seventh century with the most intensive occupation from the beginning of the twelfth century. At this time, diatoms show evidence for eutrophication and aquatic habitat changes with increases in nonplanktonic taxa. The changes in the diatom communities are attributed to the building, rebuilding, and extension of the crannog. In addition, changes in water quality were linked to changes in agricultural practices and more intensive livestock grazing in the catchment of the lough associated with the crannog's inhabitants in the Medieval period. In addition to inputs from the lough's catchment, there would have been a direct input of nutrients to the lough from the crannog itself.

Waterfronts

The collaboration between diatomists and archaeologists concerned with the reconstruction of waterfront environments is exemplified by a series of detailed studies in London where developer-funded excavations over two decades have stimulated archaeological research projects involving diatoms (Juggins, 1992; Milne et al., 1983; Sidell, 2003; Sidell et al., 2000). Prior to these studies, Roman remains lying 4 m below

the present high tide level in the outer Thames estuary led to a common assumption that the estuary lay below London during the Roman period. However, within the city the pre-Roman foreshore is buried to the north of the present riverbank. There is a time-space sequence of waterfront structures covering the last 2000 years and preserved beneath the modern waterfront (Figure 4). The halophilous, estuarine, and allochthonous marine diatoms present in sediments accumulating by well-dated quay structures clearly demonstrated that the river was tidal in the City of London during the Roman period. Juggins (1992) developed models relating diatom assemblages to salinity and taking into account the taphonomy of the diatom assemblages. This allowed the past salinity of the Thames in the city to be better estimated. More recent studies have greatly expanded the number of archaeological sites with well-dated diatom records and added to the picture of a rapidly changing river (e.g., Sidell et al., 2000). Analyses of sediments, including diatom analysis, show that the upstream progression of the tidal head of the Thames through London began in the Late Bronze Age. However, this rapid transgression is followed by a period of regression and a second transgression. During the Roman period, this resulted in continuous rebuilding of the waterfront to maintain The Port of London (Sidell, 2003). In addition, signs of possible nutrient enrichment and the effects of catchment deforestation have been detected in sediments from other waterfront and wetland archaeological sites in

Figure 4 Location and stratigraphy of Roman waterfront sediments from the City of London. Reprinted from Battarbee RW (1988) The use of diatom analysis in archaeology: A review. *Journal of Archaeological Science* 15: 621–644, with permission from Elsevier.

London. The proximity of human activities to accumulating sediments can sometimes be an unwanted complication when interpreting diatom analyses of archaeological site sediments. However, the use of archaeological artifacts and dendrochronological dating of waterfront structures has the advantage of allowing relatively accurate chronological control for many of the reconstructions.

Ancient Boats

The increasing threat of sea-level rise and coastal erosion to ancient monuments has led to an increasing interest in coastal, estuarine, and intertidal archaeology and the recent discoveries of a number of ancient boats ranging in age from the Bronze Age to the Medieval period (Figure 5). Again, dendrochronology has in many cases allowed precise dating of the boat planks (strakes) and other structural wood such as oak frames. Archaeological deductions have led to interpretation of the uses of these vessels. There is convincing evidence that several relatively large early boat finds represent sea-going craft with implications for long distance transport and trade at an early

date in prehistoric Europe. For these finds diatom analysis has been used to reconstruct the sedimentary environments in which these ancient boats came to lie and, in some cases, to look at the provenance of materials used in boat construction ([Clark, 2004](#); [Nayling, 1998](#); [Nayling and Caseldine, 1997](#); [Nayling and McGrail, 2004](#)). Diatom analysis has also been applied to ancient harbors, exemplified by analysis carried out on samples from a core sequence from Caesarea's ancient harbor with the aim of reconstructing the general salinity conditions of the sedimentary environment ([Cameron, 1999](#)).

Other Archaeological Contexts

Many unusual archaeological contexts have been analyzed for diatoms in order to assist in their interpretation. For example, diatoms from Pleistocene postoccupation layers from a cave in the Western Kalahari Desert ([Robbins et al., 1996](#)) were found to indicate flowing water. Structures such as sediments in wells ([Neely et al., 1995](#)), pits, post holes, and around fish traps ([Godbold and Turner, 1993](#)) have been analyzed for diatoms to examine the functions and environments of such features. Similarly [Denham et al. \(2009\)](#) have used diatom analysis as part of a multiproxy geoarchaeological study to interpret the fills of Holocene archaeological features at a site in New Guinea. Diatom analysis has also been used in experimental archaeology, for example, to look at the drinking habits of livestock and excretion of diatom valves to aid in the soil micromorphological interpretation of habitation floor layers. The examination of diatoms has also been applied to the investigation of ancient burials ([Foged, 1985](#)). Like the application of the methods of archaeological excavation in forensic science (forensic archaeology), diatom analysis has also become more frequently employed as a forensic technique ([Peabody and Cameron 2010](#)).

Diatoms

N G Cameron, University College London, London, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Diatoms are single-celled microscopic algae, characterized by their silica cell walls, composed of two valves and separating girdle bands. For further details, see Jones, Diatom Introduction (this volume). Diatoms are found in most aquatic habitats and in damp terrestrial habitats and in many of these habitats the diatoms represent the most abundant and diverse algal class. Diatoms are important components of the phytoplankton, benthos, and attached algal communities of marine and fresh waters. Species composition is highly sensitive to water quality and many species are habitat specific. Further, diatoms grow rapidly and under favorable conditions produce many cells within a short period. They colonize submerged surfaces quickly and many taxa show seasonality of growth. The diatom valve is persistent and allows the majority of both living and fossil taxa to be identified to the species or subspecies level. For these reasons, they have been used in a number of areas in forensic science (Peabody and Cameron, 2010).

The involvement of diatom specialists (diatomists) in forensic investigations extends back to one of the earliest recorded geoforensic studies. In Germany, during the mid-nineteenth century, the geologist and diatom taxonomist Christian Gottfried Ehrenberg (Williams and Huxley, 1998) used variation in types of sand as forensic trace evidence (Ruffell, 2010). However, as Ruffell indicates, whether Ehrenberg used his knowledge of diatom taxonomy in any subsequent forensic investigation has not been established. Although used less often in forensic ecology than techniques such as pollen analysis (Mildenhall et al., 2006), diatom analysis has become an established bioforensic technique.

The most frequent and best-known application of diatom analysis in forensic science is to assist pathologists in the diagnosis of death by drowning.

Diagnosis of Drowning

Drowning is a common cause of death. In some cases, the pathological symptoms of drowning, or the circumstances of a person's death are unclear. If drowning is suspected, or to be eliminated as a contributory cause of death, diatom analysis may be employed to provide evidence to assist the pathologist in reaching a diagnosis of the cause of death.

The diatom test for drowning has become an established forensic technique to assist in the diagnosis of drowning (Peabody and Burgess, 1984). When water enters the lungs, small particles suspended in the water may also be carried into the bloodstream and potentially throughout the body. Such particles are likely to be deposited in the capillaries of the major organs. In most natural water bodies such as streams, rivers, ponds, lakes, and in the sea, this particulate material will

include diatoms. Therefore, where diatom valves are present in sufficiently high concentrations, their presence may assist in the diagnosis of drowning and, further, in identifying the aquatic environment in which drowning occurred (see below). It should be noted that it is not uncommon to find low concentrations of diatoms in the organs of nondrowned subjects. This 'background' flora of diatoms may be taken into the body during the person's lifetime. However, the diatom species most usually found in the nondrowned can be identified and separated from those species of value in the diagnosis of drowning. For this reason, it is important that an experienced diatomist carries out the analysis.

The earliest work on diatoms for the purpose of investigating suspected cases of drowning was carried out in Hungary during the 1940s (Incze, 1942; see Peabody, 1980). The application of diatom analysis to the investigation of drowning and specialized techniques for the preparation of highly organic and potentially biohazardous samples has been reviewed recently (Peabody and Cameron, 2010).

It is important to note that the presence of diatoms in nondrowned subjects has misled many investigators unfamiliar with diatoms, and has prompted them to suggest that diatom analysis is not useful in the diagnosis of drowning (Peabody and Cameron, 2010). For example, fragments of taxa including *Coscinodiscus* Ehrenberg, *Hantzschia amphioxys* (Ehrenberg) Grunow, and *Aulacoseira granulata* (Ehrenberg) Simonsen are ubiquitous. The successful investigator must be able to recognize these and other 'naturally occurring' diatoms for what they are, and to separate the background flora from those diatoms that may be present as a result of drowning (Peabody and Cameron, 2010).

Comparison of test samples (from organs such as liver, kidney, brain, or bone marrow) with control samples (from lungs, water and possibly nonplanktonic diatom communities) representing the diatom assemblage at the suspected site of drowning and elimination of possible background diatom flora is an essential part of using diatoms to assist in the diagnosis of drowning. Figures 1 and 2 show comparisons of diatom images of two species originating from water in which drowning occurred: (1) a control sample (water and lung samples), and (2) photographs of diatom valves of the same species taken from a slide prepared from the liver. In this case, there were other indications that drowning had occurred, but diatom analysis provided supporting evidence for the diagnosis of drowning as a contributory cause of death.

In addition to the diagnosis of drowning, diatoms may be employed specifically in locating the site of drowning in cases where water currents may have moved a body some distance from its original position, or where there are indications that the body has deliberately been moved from the site of death (Ludes et al., 1999). Differences in diatom composition will reflect variation in water quality in all aquatic environments

Figure 1 (a) *Cyclotella stelligera* from a test water sample and (b) *C. stelligera* from a slide prepared from liver.

Figure 2 (a) *Rhoicosphaenia curvata* (girdle view of frustule) from a slide prepared from lung and (b) *R. curvata* (girdle view of convex dorsal valve) from a slide prepared from liver.

where there are strong environmental gradients or differences in chemistry such as pH, nutrient concentrations, salinity, or point sources of pollution such as heavy metals.

Provenance of Questioned Samples

Where materials have been submerged or there is contact with littoral or riparian sediment or vegetation, diatom analysis of sediments or other diatomaceous traces present on clothing, footwear, or vehicles can be used to identify the type of habitat involved.

Compared with nonsiliceous algae, diatoms are especially resistant to degradation and are not usually visible to the naked eye. They are, therefore, less likely to be removed from potential exhibits by an alleged offender.

In New England, USA, [Siver et al. \(1994\)](#) were able to link suspects with a lake that was the scene of a serious assault. They compared the diatom content of mud taken from suspects' and victim's shoes and freshwater pond sediment from the site of the crime. Diatom abundance, presence, or absence showed marked similarities between the samples.

Similarly diatom analysis was used to associate a murder suspect's clothing and footwear with the diatom flora of part of the River Avon, United Kingdom in which the body of a murder victim was found ([Cameron, 2004](#)). Ordination was

employed as a means of exploring and presenting the species data graphically to the jury in order to show the best analogs from among a group of test samples. Multivariate analysis of diatom data was also employed by the defence team in this case to challenge the prosecution diatom evidence ([Horton et al., 2006](#)). However, the overall concurrence of prosecution and defence diatom analytical results provided supporting evidence to assist in securing the conviction of the suspect.

Diatom analysis played a controversial role in the official investigation into the loss at sea of a British fishing vessel the FV Gaul. The Gaul and all 36 crew members were lost without trace in January 1974 in the Arctic Ocean north of Norway. In May 1974, a lifebuoy from the Gaul was recovered from the sea and diatom analysis was carried out on material taken from the lifebuoy. The diatom species present on the lifebuoy indicated an absence of deep-water marine diatoms and the presence of fresh water diatoms. At the time this led to controversy about the fate of the FV Gaul with the suggestion that the lifebuoy had been planted to disguise the fact that the loss of the ship, during the Cold War, was not accidental. However, the wreck of the Gaul was located in 1997 in the area where the ship and her crew were presumed to have been lost in heavy seas ([Steel, 2004](#)).

The standard laboratory preparation techniques developed for diatom ecological and paleoecological work ([Battarbee, 1986](#); [Battarbee et al., 2001](#)) can often be adapted for these

kinds of forensic study. However, [Uitdehaag et al. \(2010\)](#) made a systematic comparison of the efficacy of different methods used to extract diatoms from cotton clothing. Rinsing items with ethanol was found to be an effective and reproducible extraction method for both qualitative and quantitative analysis of diatoms deposited on cotton clothing.

Diatomite

The use of diatomite, both in manufacturing processes and as a component of finished products, leads to potential uses in forensic investigations. In addition, other raw materials may contain diatoms, for example, diatomaceous clays used in the manufacture of ceramics. Pottery, tile, or brick, for example, may retain diatoms where firing temperatures are low. However, the most important diatomaceous raw material is diatomite. This is a porous, low-density, sedimentary rock formed by the accumulation and compaction of diatoms which may comprise 90% or more of the dry weight of the rock. The physical properties of diatomite have led to its use in many commercial applications, the most common being for the filtration of liquids or as a filler, for example, in paints. Other uses of diatomite include insulation (fire bricks), fine abrasion (in some toothpaste and polishes) and as a pesticide. Freshwater and marine diatomites are mined in various parts of the world and range in age from the late Cretaceous to the Holocene so there may be a great deal of variation in the diatom assemblages present. The estimated total annual world production of diatomite is approximately 2 million metric tons ([Harwood, 2010](#)).

Diatomite derived from various materials has, therefore, been employed by forensic scientists to provide evidence of association. At present, commercial sources of diatomite are restricted to a few large sites. Consequently, the same raw material, potentially having a similar fossil diatom flora, can be used in the manufacture of a large number of products. However, forensic scientists have, for example, utilized diatoms from paint and polishes to provide evidence of association ([Peabody and Cameron, 2010](#)).

Diatomite was formerly used as a fireproof packing material between the outer casing and inner compartment of safes. If this type of safe is broken open, diatomite may contaminate clothing with a high concentration of diatom valves. The comparison of diatom assemblages in such cases will produce highly distinctive traces because diatomite safe ballast is likely to have been taken from former diatomite workings and it is unlikely that an individual would have this material on clothing by chance ([Peabody and Cameron, 2010](#)). In the past, nitroglycerine was absorbed in diatomite as a means of safe transport and this form of the explosive is still used occasionally ([Harwood, 2010](#)) and, therefore, this has the potential for use as forensic trace evidence.

[Ruffell and McKinley \(2008\)](#) describe a case where material suspected to be diatomite was presented to forensic geologists in Northern Ireland. Seized from a fuel storage depot, the possible diatomite might have been used to absorb red dye used in the United Kingdom to mark diesel fuel that has a lower tax duty and is allowed for use only in approved industrial applications. It was claimed by the suspected 'fuel launderers' that the material was clay – Fuller's Earth – used for the

legitimate purpose of soaking up oil spills. However, in this case the definitive separation of Fuller's Earth from diatomite was complicated by the presence of a proportion of siliceous fossils (including diatoms) in the Fuller's Earth, and by a fraction of clay in the diatomite. It is not indicated whether microscopic examination of the disputed substance was made to determine the diatom species composition.

[Ruffell and McKinley \(2008\)](#) also cite the use of diatom analysis to investigate a 1967 case of kidnapping in Beverly Hills, CA ([Cleveland, 1973](#)). After the release of the victim, a footprint on the carpet of an abandoned vehicle used to collect the ransom, was found to be of diatomite. Two common sources of diatomite in the western United States are fossil freshwater diatom assemblages from dry lakes (e.g., in Nevada) and Miocene fossil assemblages from the Monterey diatomite, a marine formation. A mixture of both these diatomite types was present in the diatomite footprint, as well as a smaller number of contemporary diatoms. A search identified an abandoned quarry and a testing laboratory where fossil marine diatomite had been quarried and freshwater diatomite was also imported for analysis. During storage at the site, mixing of the two diatomite types occurred, as well as the contemporary growth of diatoms in rainwater pools on the ground. Examination of one suspect's footwear, the imprint matching that in the abandoned car, and another vehicle with a similar mix of diatoms on the exterior, associated this suspect with the quarry where the kidnap victim had been held. Diatom analysis, therefore, provided some supporting evidence in the conviction of the kidnapper in this case.

Soils and Aerophilous Diatoms

Diatoms are not restricted to growing in fully aquatic habitats and the diatom communities of soils and other damp habitats are dominated by specialized desiccation-tolerant taxa (for a review see [Johansen, 2010](#)). Therefore, diatoms that are present as a component of forensic soil samples ([Pye, 2007](#); [Rawlins et al., 2006](#)) do not necessarily have an aquatic origin and detailed identifications of the species concerned are required to determine the species provenance. Although careful diatom analysis combined with statistical analysis of this type of soil diatom assemblage has been used successfully to provide evidence of association in forensic cases (van Dam, unpublished data), this area of diatom study has probably been underemployed elsewhere. Further work on the ecology of such aerophilous diatom communities is required. [Sugita et al. \(2004\)](#) examined microalgae in three soil samples taken from roads for the forensic discrimination of soils. Culture media were used as a means of growing and separating the algal species from the soil matrix. However, in this case cyanobacteria and green algae were observed in all the samples while diatoms occurred in only one of them. The three soil samples were successfully discriminated by the comparison of algae.

Period of Immersion

The use of diatoms in estimating the time elapsed since a body (postmortem submersion interval) or object was first

immersed in water has been the subject of some recent studies. These are analogous to methods used in diatom ecology where the growth of diatoms on inert substrata submerged in water is used as a means of environmental monitoring. This is similar in principle to the use of forensic entomology in estimating the time of death when a significant period has elapsed before the discovery of a body. Experimental work on forensic pathology (Casamatta and Verb, 2000; Zimmerman and Wallace, 2008) indicates that species diversity and sequence of diatom species and other algal taxa colonizing submerged animal carcasses has some potential for estimating the period of submersion of a body or other materials.

Conclusion

A number of characteristics of diatoms, including their wide-spread presence in water, sensitivity to water quality, high species diversity, habitat specificity, their use in manufacture, and good potential for preservation, suggest that this group of algae has further potential for use in forensic science. The invisibility of valves to the naked eye and the fact that diatoms are not well known to the layman are also useful attributes. Mildenhall et al. (2006) point out the importance of careful subsampling to avoid compromising evidential and control samples through destruction or contamination, particularly where a number of complementary forensic techniques are to be applied (e.g., diatom and pollen analysis). The use of diatom biogeographic data from large databases (e.g., Battarbee et al., 2000) prepared for environmental research has potential for use in future forensic investigations.

Marine Antarctic Waters: The Southern Ocean Siliceous Ooze Belt

The southern high latitudes play a critical role in the global climate system. Advances in the understanding of the paleoceanographic and cryospheric evolution of the Southern Ocean and Antarctica are helping us comprehend global climate change on a number of timescales. Diatoms are arguably the best fossil group for unraveling Antarctic climate change because they are prolific in the Southern Ocean – the area between the coast of Antarctica ($\sim 70^\circ$ S) and the subtropical front (STF; $\sim 40^\circ$ S; [Figure 1](#)) – contributing up to 75% of Southern Ocean production, despite this being a high-nitrate low-chlorophyll (HNLC) region. Such high diatom production in the surface waters, combined with a high export flux to the seafloor, has characterized the Southern Ocean as the world's main sink for biogenic opal (biosilica) since at least the early Pliocene (~ 4.5 million years ago, my; [Cortese et al., 2004](#)), and therefore a key regional component in the silica cycle. In particular, the area beneath the Antarctic Circumpolar Current (ACC), a major link in the thermohaline circulation, comprises a continuous belt of opal completely encircling Antarctica between 45° and 60° S ([Figure 2](#)). Diatomaceous sedimentation has been occurring within this belt more or less continuously since at least late Miocene times. Today, the nutrient-rich Southern Ocean supports a unique flora comprising at least six planktonic endemic species according to [Zielinski and Gersonde \(1997\)](#): *Eucampia antarctica*, *Fragilariopsis curta*, *F. kerguelensis* ([Figure 3](#)), *F. separanda*, *Shionodiscus gracilis* (cited as *Thalassiosira*), and *Thalassiosira lentiginosa*. Here, the Polar Frontal Zone (PFZ; [Figure 1](#)) acts as a major

geographic barrier to the migration of planktonic diatoms, separating cooler water Antarctic species to the south from warmer water subantarctic species to the north.

The Quaternary fossil diatom record of the Southern Ocean is generally well known, comprising mostly, but not exclusively, extant (living) species in high abundance. For example, [Zielinski and Gersonde \(1997\)](#) report diatom concentrations of $50\text{--}200 \times 10^6$ valves g^{-1} within surface sediment of the Atlantic sector beneath the ACC. Nutrient availability, temperature, water column stability, influence of sea ice, and grazing pressure are the main factors controlling distribution (e.g., [Crosta et al., 2005](#)). A siliceous ooze belt where diatoms are well preserved is bound north and south by sediments containing less well-preserved diatoms ([Figure 2](#)); carbonate-rich diatomaceous sediments to the north; and silty, terrigenous-rich diatomaceous clay to the south including the shelf regions. These boundaries are defined by oceanographic parameters – the modern PFZ ([Figure 1](#)) to the north and the mean position of the winter sea-ice edge (WSI; [Figure 1](#)) to the south. A similar relationship is inferred for the past, for which diatom records indicate a dynamic, climate-controlled history. Oceanographic parameters are sensitive to climate change and have shifted position, notably north or south, during the past, thereby influencing the position of the siliceous ooze belt. An added complexity is that these past frontal shifts and changes to the position of the sea-ice edge were not uniform or synchronous in all sectors of the Antarctic region. Therefore, through time, climate change has also indirectly altered the shape, or pattern, of the siliceous ooze belt to a certain degree. South of the siliceous ooze belt – across the Antarctic continental shelf – biogenic silica production and deposition also occurred during

Sea ice related species. *Palaeogeography, Palaeoclimatology, Palaeoecology* 223: 93–126. Copyright (2005), with permission from Elsevier.

the Quaternary, but records are patchier, diluted by high amounts of terrigenous material, and generally less well preserved than in open ocean regions due to the influence of glacial and shelfal current processes. However, there are unique regions on the shelf where diatom productivity and flux were exceptionally high during the last deglaciation and Holocene resulting in distinct seasonal layering.

Applications of Quaternary Marine Antarctic Diatoms

Despite their preservation issues, marine diatoms are remarkably useful tools for climate reconstruction because they reflect their life environment and are normally the first microplankton group to respond to environmental change. Their use in paleoenvironmental reconstruction is perhaps most valuable for marine sediments recovered from below the calcium carbonate compensation depth (CCD) and in the high-latitude regions such as the Southern Ocean. In these environments, siliceous microfossils (mostly diatoms, and silicoflagellates

and radiolarians as well) prevail over calcareous microfossils (nannofossils and planktonic Foraminifera) because carbonate is not preserved below the CCD (preservational advantage), and reproduction of calcareous-walled microplankton is severely inhibited in polar waters (environmental advantage). Therefore, Antarctic marine diatoms are arguably the most reliable microfossil group for reconstructing past Southern Ocean and Antarctic shelf environments. Of critical interest are past fluctuations in sea-surface temperature (SST; e.g., Crosta et al., 2004; Zielinski et al., 1998), latitudinal oceanic frontal migration (e.g., Burckle, 1984; Gersonde et al., 2005; Kemp et al., 2010), sea-ice fluctuations (e.g., Armand and Leventer, 2009; Crosta et al., 1998; Gersonde et al., 2005), productivity and opal depositional history (e.g., Cortese et al., 2004), the role of diatoms in biogeochemical processes such as the cycling of major nutrients (i.e., silica, carbon, nitrogen, phosphorous), and the carbon pump, involving stratification (e.g., Kemp et al., 2006) and/or upwelling-induced carbon dioxide drawdown. To this end, there has been significant progress in recent days in assessing modern or

Figure 2 Siliceous ooze belt of well-preserved diatoms in surface sediments around Antarctica (black dots within the shaded area). Poorly preserved diatoms are indicated by white dots. Copyright (1984), with permission from Elsevier.

submodern species distribution patterns (biogeography) and other modern parameters, and in the refinement of Antarctic diatom-based statistical techniques that link the past with the present. These techniques have advanced our understanding of the main environmental drivers controlling species abundance. In this way, Antarctic diatoms are the key to elucidating the climatic and oceanographic history of the Southern Ocean. Further, the sort of information they provide is valuable for feeding back into, and improving, climate models that ‘hind-cast’ past environmental conditions. Importantly, because most Quaternary Antarctic species are extant, ecological-based applications can be applied to the recent past with confidence. Quaternary marine Antarctic diatoms are also widely used in biostratigraphy for both offshore regions and the Antarctic shelf (e.g., Barron, 2003; Cody et al., 2008). Across the shelf, they can also help elucidate sea-level changes, past glacial processes, and ice-sheet history (e.g., Naish et al., 2009). North of the Southern Ocean, an interesting but somewhat underdeveloped application is in their use for tracing Antarctic-source bottom water in the world’s ocean (e.g., Stickley et al., 2001).

Encompassing the world’s richest source of biogenic opal, the Southern Ocean and Antarctic shelf provide enormous opportunity to understand past Antarctic environments and climate change, promoting a wealth and diversity of studies involving Quaternary (and older) marine Antarctic diatoms (see Jordan and Stickley, 2010; Leventer et al., 2010 for comprehensive reviews). This has been made possible by several highly publicized, large-scale multinational drilling expeditions to the Southern Ocean and Antarctic shelf over the past 40 years or so (Figure 4): most recently IODP (and its predecessors ODP and DSDP), ANDRILL (and earlier Ross Sea drilling by CRP, CIROS, MSSTS, and DVDP), SHALDRIL, IMAGES (see bibliography for explanation of acronyms and project websites for references), as well as numerous smaller scale multinational and nationally funded expeditions.

It is not possible to discuss all these studies here; instead, the reports and areas of research that have widespread importance for the understanding of the Quaternary history of Antarctica and the Southern Ocean are summarized. Further reading on these and other topics from these publications and

Figure 3 Light microscope image (plane polarized light) of endemic diatom *Fragilariopsis kerguelensis*, one of the main contributors to biogenic opal in Southern Ocean sediments. Image by E.J. Maddison (Cardiff University, UK) taken from late Quaternary laminated sediments of the East Antarctic Margin. Lower specimen is 50 μm in length.

references therein is encouraged. The focus is on (1) reconstructions of past sea-surface conditions including biogeography and primary productivity, sea-ice history, SST, and oceanic frontal migration; (2) Antarctic diatoms as tracers of bottom water; (3) ice-sheet history and glacial processes; and (4) biostratigraphy.

Reconstructions of Past Sea-Surface Conditions

Advances have been made in recent days in mapping the biogeography of modern (or submodern) marine diatoms in the Southern Ocean and Antarctic shelf seafloor sediments with respect to environmental controls. These ‘core-top’ sediments are taken to reflect ‘modern day’ sedimentation that may in reality represent sedimentation averaging the last several hundred years or so, depending on location – this fact is usually acknowledged in the better reports, and is generally acceptable for the resolution and timescales involved in most environmental reconstructions for the Quaternary. The assessment of hydrographic and cryospheric parameters controlling the temporal and spatial patterns in the productivity of marine diatom species living in the overlying surface waters is a valuable and necessary goal for reproducible paleoenvironmental reconstructions. These modern diatom data sets, or training sets, have been analyzed by a variety of statistical techniques and transfer functions have been created. Techniques such as the modern analog technique and the generalized additive model (see Crosta and Koç, 2007 for review and references) have enabled quantitative reconstructions of SSTs and seasonal sea-ice patterns for the Quaternary. These methods follow the assumption that the biogeographic variability of species preserved in the surface sediments reflect the surface-water hydrology and, therefore, may be used as a proxy for paleoenvironmental variability. The merits of assessing past SSTs and sea-ice patterns are clear: the warming and cooling of the ocean surface is a primary gauge for climate change, while sea ice (coverage, duration, and concentration) is especially important

for climate models because of its critical feedback effects and the energy exchanges associated with its growth and decay, as well as its impact on thermohaline circulation. As most diatom flux to seafloor sediments of the Southern Ocean occurs during austral summer (the ‘growing season’), relationships between diatom distributions and environmental parameters are best made with reference to summer conditions. However, reference to winter conditions is equally important as it provides a means to contrast seasonal extremes as well as factoring in the controllers for particular species distributions. Care must be taken, however, in generalizing for all areas of the circum-Antarctic because as Pike et al. (2008) showed in their statistical comparative study of surface water and sea-ice samples, and core-top sediments on the West Antarctic Peninsula shelf, seafloor sediments of this region more closely resemble spring diatom production rather than summer. In another example, Armand et al. (2008) describe the north-eastern Kerguelen Plateau as having an ‘island mass effect’ on diatom species distributions in core-top sediments that deviate from those previously reported for the permanently open ocean zone (POOZ; Figure 1; see below) that includes the Kerguelen Plateau.

Biogeography and primary productivity

Until the last decade or so, understanding of the relationship between the distribution of Antarctic diatoms in core-top sediments and surface-water hydrology was limited to a few early reports from the 1960s and 1970s. Although pioneering, these reports either accounted for a limited area of the Southern Ocean or covered a wider area in less detail. One of the more useful later reports is that by Burckle (1984). He mapped species distributions and preservation from core tops in all sectors of the Southern Ocean, covering its entire latitudinal range from nearshore to just north of the present day position of the STF (Figures 1 and 2). Although the dataset was relatively small (55 core tops; nine significant species) and the data points relatively scattered (Figure 2), Burckle (1984) produced one of the first distributional studies to cover the entire circum-Antarctic, and he attempted to statistically quantify the relationship between species distribution and environmental parameters. Later, Zielinski and Gersonde (1997) provided the first truly comprehensive modern species-specific distributional dataset for the Atlantic Sector of the Southern Ocean. They clearly showed that the biogeography and abundance of 35 significant diatom species in this region are closely related to summer SSTs and the extent of sea-ice cover, and therefore concluded that distributional patterns undoubtedly have paleoenvironmental significance.

A more extensive biogeographical dataset in terms of both coverage and detail is provided in a set of linked research papers by Armand et al. (2005), Crosta et al. (2005), and Romero et al. (2005). Their comprehensive modern database (Diatom Database 228 or DD228) highlights the importance of using fossil diatoms to reconstruct past environments and indicates that maximum abundances (indicating high primary productivity) of individual diatom species reflect narrow ranges of environmental conditions. Appropriately, Armand et al. (2005) broaden the use of sea-ice control by factoring in its concentration and duration, and not merely its presence or absence. This gives a much more sophisticated and

Figure 4 Location of key drill sites and drilling regions of the Southern Ocean and Antarctic shelf mentioned in the text, relative to physiography and modern oceanography. Adapted from [Figure 1](#) by [Cody et al. \(2008\)](#) with some additions. See 'International drilling projects cited in text' for acronyms. Reprinted from Cody RD, Levy RH, Harwood DM, and Sadler PM (2008) Thinking outside the zone: High-resolution quantitative diatom biochronology for the Antarctic Neogene. *Palaeogeography, Palaeoclimatology, Palaeoecology* 260: 92–121. Copyright (2008), with permission from Elsevier.

complete view of the relationships between diatom distribution and environmental parameters. These three interlinked papers also cover a much wider area than previous studies, and the biogeography of 32 major diatom species/taxa in 228 core-top sediment samples from all sectors of the Southern Ocean from the coast to just north of the STF was mapped ([Figure 1](#)). For example, the distribution pattern of the abundance of the endemic diatom *F. kerguelensis* ([Figure 3](#)), one of the main contributors to biogenic opal in Southern Ocean sediments, indicates its highest abundance within a SST range of between +1 and +8 °C ([Figure 5](#)). In DD228, each diatom species is defined as having the highest affinity with one of three zonally distinct regions: (1) the seasonal sea-ice zone (SIZ; [Figure 1](#)) between the maximum average winter and summer sea-ice edges, where sea ice occurs annually; (2) the POOZ between the maximum average WSI edge and the subantarctic front (SAF; [Figure 1](#)); and (3) the tropical/subtropical zone (STZ;

[Figure 1](#)) north of the SAF. Although all 32 diatom taxa occur throughout the study region, each to a greater or lesser degree, the correlation of their geographic patterns with sea-surface parameters illustrates the principal environmental control on the occurrence and abundance of each species (see [Table 1](#), sea-ice diatoms). For the SIZ and POOZ, these controls are summer (February) SSTs and sea-ice coverage in terms of (i) its concentration (% of water covered) during seasonal extremes (summer and winter) and (ii) its annual duration (months per year). In the STZ, the main controller is warmer SSTs and minimal influence by sea ice.

Another widely applied indicator of primary productivity is the abundance and distribution of *Hyalochaete Chaetoceros* resting spores (CRS). One of the first applications in the Antarctic realm was in the study of laminated sediments from the Antarctic Peninsula. High abundances of CRS are normally taken to reflect an influx of nutrients causing a bloom of vegetative *Hyalochaete Chaetoceros* that leads to resting spore

formation and flux. CRS are often associated with upwelling systems and oceanic fronts in the world oceans, but in Antarctica, they are more likely to indicate ocean stability associated with sea ice (Armand and Leventer, 2009).

Sea-ice history, SSTs, and ocean frontal migration

Past sea-ice patterns and SSTs should be considered together as they are interrelated, albeit not necessarily linearly over long timescales. For example, Crosta et al. (2004) showed, in their quantitative diatom study of the Indian sector of the Southern Ocean, that during the transition from interglacials to glacials, sea-ice expansion lagged the SST decrease by approximately one thousand years (ka), while sea-ice retreat was almost synchronous with the SST increase at glacial–interglacial terminations.

Sea ice (Figure 6) provides an important and vast habitat for cryophilic Antarctic diatoms, supporting rich assemblages of these uniquely adapted extremophiles or the so-called sea-ice diatoms throughout the growing season. At the height of their growth, populations of sea-ice diatoms dwelling in the lower layers of sea ice can become so dense that they discolor the underside of the ice a yellow-brown or yellow-green color. Austral summer (February) sea ice (or multiyear ice) covers an area of approximately $3\text{--}4 \times 10^6 \text{ km}^2$, expanding in winter (August) to approximately $19 \times 10^6 \text{ km}^2$ (Figure 1) on average. Although sea ice inhibits normal surface water production and sedimentation, it stimulates huge blooms of diatoms at the edge of the sea ice and in the surrounding waters (the marginal SIZ) during the spring melt. The so-called sea-ice-related (or sea-ice-associated) taxa involved in these spring melt blooms, such as *F. curta* and *F. cylindrus* (Figure 7), are routinely used to trace winter sea-ice patterns for the Quaternary via a number of techniques, ranging from simple species presence/absence to more complex quantitative methods. Similarly, the presence of *F. obliquecostata* and a general fall in biogenic sedimentation may be used to trace summer sea-ice extent (e.g., Crosta and Koç, 2007; Gersonde et al., 2005). All techniques assume that the paleoecology of the extant species was the same as that observed for its living counterpart (e.g., Armand and Leventer, 2009). Leventer et al. (2010) list a number of other important sea-ice-related diatom taxa widely used to reconstruct sea-ice patterns for the Quaternary and Holocene, and go on to describe some of the pioneering and highly cited reconstructions, a detailed and vast subject in itself. The discussion elsewhere in this encyclopedia highlights studies where ultra-high resolution (i.e., seasonal) sea-ice reconstruction is possible from laminated circum-Antarctic sediments. Sea-ice diatoms also produce specific biomarkers that have been used to infer past sea ice. Further, one of the more interesting aspects of sea ice and sea-ice-related diatoms is that they are an important source of dimethylsulfide (DMS), a molecule implicated in the formation of clouds. Therefore, an understanding of sea-ice-related diatom production may have important implications for atmospheric climate, as well as cryospheric, feedbacks.

Zielinski et al. (1998) developed a rigorously tested SST transfer function of summer SST estimates for a core located in the Atlantic and western Indian sector of the Southern Ocean over the last ~ 200 ka. Bianchi and Gersonde (2004) later used this transfer function to reconstruct detailed trends in SST from the South Atlantic over the past 18 ka. Qualitative SST and sea-ice reconstructions are also possible through the documenting of changes in valve morphometrics, ornamentation, areolation, and/or degree of silicification of some species, for example, *F. kerguelensis* and *F. curta* (see Leventer et al., 2010, for review).

Other studies have concentrated on reconstructing conditions during particular time-slices, such as the Last Glacial Maximum (LGM). For example, Crosta et al. (1998) were the first to use the modern analog technique to quantitatively reconstruct circum-Antarctic sea-ice patterns from marine diatoms in terms of annual duration (months per year) at the LGM. In their comprehensive ‘state-of-the-art’ compilation of published and new datasets, Gersonde et al. (2005) provide the most up-to-date estimation of summer SSTs and both summer and winter sea-ice distribution patterns in the

Figure 8 Sea-ice distribution at the EPILOG Last Glacial Maximum (E-LGM) time-slice compared to modern conditions. E-LGM-WSI, maximum extent of winter sea ice at the LGM (September, concentration >15%). M-WSI, maximum extent of modern winter sea ice (September, concentration >15%, see Gersonde et al. (2005) for reference). Values indicate estimated winter (September) sea-ice concentration in percent derived with the modern analog technique and the generalized additive model. Legend: (1) Large dots – concomitant occurrence of cold-water indicator *Fragilariopsis obliquecostata* (>1% of diatom assemblage) and summer sea ice (February, concentration >0%) interpreted to represent sporadic occurrence of E-LGM-SSI (= maximum extent of summer sea ice at the LGM); (2) medium dots – presence of winter sea ice (September, concentration >15%, diatom winter sea-ice indicators >1%); (3) small dots – no winter sea ice (September, concentration <15%, diatom winter sea-ice indicators <1%). Data compilation is presented in Table 3 of Gersonde et al. (2005). M-SSI, maximum extent of modern summer sea ice. Reprinted from Gersonde R, Crosta X, Abelmann A, and Armand L (2005) Sea-surface temperature and sea-ice distribution of the Southern Ocean at the EPILOG Last Glacial Maximum – A circum-Antarctic view based on siliceous microfossil records. *Quaternary Science Reviews* 24: 869–896. Copyright (2005), with permission from Elsevier.

Southern Ocean at the LGM, based on quantitative analysis of diatoms and radiolarians. Based on new data and reference datasets of several previously published works, Gersonde et al. (2005) applied three statistical methods to 122 marine cores located in all sectors of the Southern Ocean to quantitatively reconstruct the glacial Southern Ocean at the EPILOG (environment processes of the Ice Age: land, ocean, glaciers) LGM time-slice (23–19 calendar years before present, cal ka BP).

Their results indicate that at the EPILOG LGM, the maximum winter sea-ice extent (at a concentration of >15%) reached as far north as nearly 47° S in the Atlantic and Indian sectors, but only to 57° S in the Pacific (Figure 8). This equates to a total, asymmetric, EPILOG LGM circum-Antarctic winter sea-ice field of approximately 39 million km², a doubling of the area compared to the present, that agrees with earlier estimations (e.g., climate long-range investigation, mapping,

and prediction, CLIMAP). However, unlike previous studies, they suggest increased seasonality at the LGM based on the large differences between the extent of the winter and postulated summer sea-ice fields and those of today (Figure 8). In addition, their estimation of EPILOG LGM summer SSTs indicates a northward migration of the LGM polar front (PF; Figure 1) by 4° and 5°–10° latitude in the Atlantic and Indian sectors, respectively (Figure 8), with the strongest cooling (4–6 °C decrease) occurring in these sectors in the modern subantarctic zone (SAZ; Figure 1). These are larger estimates than previously reported (e.g., CLIMAP), and Gersonde et al. (2005) conclude a similar northward shift in the LGM SAF in the Atlantic and Indian sectors but only a relatively minimal northward shift of the LGM STF, leading to compression of the SAZ and steepened thermal gradients. However, their data from the Pacific sector implies reduced cooling here and therefore possible nonuniform cooling (and asymmetric frontal movement) of the glacial Southern Ocean at the LGM.

The authors advocate using integrated multiproxy approaches (i.e., diatom proxies used in conjunction with other biological as well as nonbiological proxies) for paleoceanographic reconstruction and suggest consultation of the reviews by Röthlisberger et al. (2010) and Armand and Leventer (2009) on the use of sea-ice proxies, and that by the MARGO Project Members (2009) on SST proxies at the LGM.

Antarctic Diatoms as Tracers of Bottom Water

Marine planktonic diatoms endemic to the Southern Ocean can be transported out of the Antarctic waters into the world's oceans via Antarctic Bottom Water (AABW). This is possible where surface-dwelling diatoms are entrained into downwelling AABW during its formation in the Weddell and Ross Sea gyres and on the shelves around the Antarctic continent. Entrained diatoms subsequently settling out along the flow path become effective tracers of this deep current. The process has clearly operated in recent times, as demonstrated by the presence of Antarctic endemic diatoms in core-top sediments along the AABW flow path north of the STF in the southwest and central Pacific (Stickley et al., 2001) and the southwest Atlantic (Jones and Johnson, 1984). In these locations, displaced endemic diatoms can comprise the majority of the sediment assemblage, while they are absent from core-top sediments located in overlying water masses (e.g., the North Atlantic Deep Water, NADW). Endemic diatoms displaced by AABW have also been noted in surface and core sediments as far as 60° N (L.H. Burckle and C.E. Stickley unpublished data).

Significant abundances of displaced endemic diatoms have been found in late Quaternary (last ~200 ka) core sediments within the AABW flow path in the southwest Pacific (Stickley et al., 2001) and southwest Atlantic oceans (e.g., Jones and Johnson, 1984). Along with the stable isotopic signal from biogenic carbonate, these assemblages help provide information on the production and flow history of AABW to these oceanic basins. This is of interest as AABW plays a key role in the climate system, being one of the main transporters of heat and salts around the world's oceans. A higher abundance of displaced diatoms indicates higher AABW flow. For example, Jones and Johnson (1984) found that for the southwest Atlantic, displaced diatoms are more abundant during

interglacials (higher AABW flow) than during glacial maxima (lower AABW flow). Unlike stable isotopes, displaced endemic Antarctic diatoms provide unequivocal evidence of bottom water provenance in the North Atlantic. Furthermore, in the southwest Pacific, down-core variations in the abundance of displaced open-water diatoms (e.g., *F. kerguelensis*; Figure 3; *T. lentiginosa*) versus sea-ice-related diatoms (e.g., *F. curta*, *F. cylindrus*; Figure 6) may indicate temporal switches in AABW source (open-water-derived versus shelf-derived, respectively) through the late Quaternary (Stickley et al., 2001).

Ice-Sheet History and Glacial Processes

The long history of Antarctic shelf drilling programs, mostly in the Ross Sea region (see bibliography), and also along the East Antarctic Margin, have recovered diatom-bearing deposits, which are helping to elucidate both long-term and shorter term cryospheric evolution and development through the current 'icehouse' world, including variations in both the East and West Antarctic ice sheets. Results have revealed Milankovitch to seasonal pacing in ice-sheet dynamics. Some of the more recent and groundbreaking multiproxy-based research studies on ice-sheet history employ species and total abundance changes in Antarctic diatoms over long and shorter time intervals.

Anticipated results from IODP Expedition 318 to the adjacent Wilkes Land Margin in 2010 (Expedition 318 Scientists, 2010) are expected to provide high quality seasonal to longer timescale changes in the East Antarctic Ice Sheet, whereas on-going results (including numerous diatom studies) from the high profile ANDRILL program are unlocking the evolution of the West Antarctic Ice Sheet on a range of timescales. During its first drilling season (2006–7) alone, ANDRILL drilled over 1280 m of sediment core (the AND-1B core) with overall 98% recovery, representing the longest and most complete geological record from the Antarctic continental margin to date, archiving obliquity-paced (40 ka cycles) Pliocene and Pleistocene West Antarctic ice-sheet oscillations (Naish et al., 2009). Upper Miocene to Pleistocene sediments were recovered that comprise alternating diatomites of ~1–100 m thickness and glacial diamictites, with episodic volcanics. The upper ~600 m of the AND-1B core are diatom-rich (Pliocene–Pleistocene). The diamictites represent glacial advance (glacials), while the diatomites, most of which are nearly pure biogenic silica and often laminated, record high diatom productivity in open-water marine environments during climatic phases that were generally warmer than present (interglacials) with minimal summer sea ice (Naish et al., 2009; Scherer et al., 2007). The diatoms in the AND-1B core are generally low in diversity and often fragmented, consistent with subglacial or sedimentary compaction (Scherer et al., 2007). A careful analysis of the abundance and style of fragmentation may reveal glacial processes (see Jordan and Stickley, 2010 for review and references). Analysis of diatom fragments from diamictites in other localities and experiments indicate that valve characteristics remain identifiable even after degradation by grounded ice and subglacial transportation, that is, sub-ice streams even if shearing is intense. The relative proportion of centric to pennate diatom valves may distinguish glacially sheared sediments from undisturbed hemipelagic sediments, and from sediments fragmented by normal stress compaction on the Antarctic

continental shelf. Unequal changes in absolute and relative diatom abundances occur with compaction and shearing, depending on the shape and size of the diatom; also, the ratio of unbroken centric to pennate diatoms may gauge past sub-ice stream shearing (proportionally more centrics indicate more shearing). Further, by analyzing the relative proportion and type of reworked diatoms to *in situ* diatoms, in combination with whole to fragmented valves, it is possible to classify and distinguish between late Quaternary tills deposited beneath ice streams and those emplaced by slow-moving ice, information that is important in ice-sheet reconstructions (see [Jordan and Stickley, 2010](#), for references).

Southern Ocean Diatom Biostratigraphy

Since the rise of the diatoms in the Mesozoic Era, climate change and tectonism have influenced their evolution, diversity, migration, and biogeography, as niches and environments are created and destroyed (see [Jordan and Stickley, 2010](#) for review and references). Planktonic marine diatoms have undergone several relatively rapid, stepwise, turnover (evolutionary) events during the Cenozoic and as such are excellent tools for biostratigraphy. In turn, excellent biostratigraphy (biochronology) is necessary to elucidate the timing of climatic and oceanographic events. Diatoms are perhaps the most useful and widely used fossil group in age determination for Neogene (last ~23 my) Southern Ocean sediments. Since the early 1970s, several diatom zonation schemes have been, and continue to be, developed through offshore drilling by DSDP and ODP, and more recently, by IODP, in early 2010 ([Expedition 318 Scientists, 2010](#)). The more recent and useful Southern Ocean zonation schemes are integrated with magnetostratigraphy, allowing diatom events to be tied to the geomagnetic polarity timescale (GPTS), giving geochronologic as well as chronostratigraphic information. Such calibrations are key to understanding the timing of climate events through a multiproxy approach, and can highlight diachroneity in biostratigraphic events across regions, leading in turn to a better understanding of evolution and biogeography. For example, due to latitudinal gradients in surface-water parameters, the distribution of late Neogene and Quaternary marker diatoms is not the same north and south of the PFZ ([Figure 1](#)), leading to separate late Pliocene and Pleistocene (Quaternary) zonations for sites north and south of the PFZ (see [Cody et al., 2008](#), for references).

High resolution diatom biochronologies constructed by the methods used by [Barron \(2003\)](#) and [Cody et al. \(2008\)](#) allow a reasonable estimation of the rates of evolutionary turnover of planktonic diatom species for the Neogene (including Quaternary) Southern Ocean, as well as an estimation of their diversity, in approaches that incorporate reduced preservational and recording bias. The best biostratigraphic events (datums) are those marking the range bases (or the first stratigraphic occurrence, FO) of abundant and widespread species. Range tops (or the last stratigraphic occurrence, LO) of species are also useful, but reworking can mask the true stratigraphic position of these bioevents, so more skill is required in the assessment of LO datums. Compared to the Southern Ocean offshore regions, diatom biostratigraphy for marginal marine Antarctic shelf sediments is more problematic and therefore relatively

underdeveloped – a reflection of poorer preservation, lack of oceanic marker species, reworking, and the effects of glacial processes such as ice-grounding events that truncate lithological units. Despite these issues, significant progress in developing Antarctic-shelf diatom zonation schemes has been made in recent years, largely through the unprecedented success of the first two ANDRILL shelf drilling seasons in the Ross Sea region during 2006–7 and 2007–8 (e.g., [Scherer et al., 2007](#); [Winter et al., 2010](#)). These works add to and build on earlier studies from a suite of previous Antarctic shelf drilling programs in the Ross Sea (CRP, CIROS, MSSTS, DVD, DSDP; see [Scherer et al., 2007](#) and [Winter et al., 2010](#), for references) and drilling in the NW Weddell Sea (SHALDRILL).

The comprehensive high-resolution quantitative diatom biochronology for the Antarctic Neogene by [Cody et al. \(2008\)](#) is currently the most robust biostratigraphic scheme for the Southern Ocean for any fossil group. Their scheme allows age calibration to within an average of ± 80 ka – an order of magnitude greater in temporal resolution than earlier approaches. Further, unlike zonation schemes that tend to be geographically limited, the outputs of the quantitative approach by [Cody et al. \(2008\)](#) are applicable over a much wider area of the Southern Ocean, from the shelf to north of the PF. [Cody et al. \(2008\)](#) statistically integrate diatom biostratigraphy, magnetostratigraphy, and tephrostratigraphy from 32 offshore and shelf drill sites around the Southern Ocean, and present the correlation of these parameters as a constrained optimization (CONOP) – similar in approach to that for multidimensional graphic correlation. Their approach establishes a precise, reproducible biochronology that takes into account the quality of the original records (removing unreliable data) such as recovery and preservation, and gives confidence intervals on age assignments. Two complementary models are presented, based on different assumptions about reworking, which give independent estimates of average local ranges and total regional ranges of 116 fossil diatom taxa in the southern high latitudes covering ~20–0.06 my (~60 ka; [Figure 9](#)). Sixty-three diatom datums resolve the Quaternary (taking the base of the Pleistocene to be 2.59 my). As the CONOP model incorporates biostratigraphies from nearshore and offshore sites, it heralds better correlation between shelf and offshore sedimentary sections. Indeed, the ‘on-going fluid model’ presented by [Cody et al. \(2008\)](#) is constantly being improved as new diatom biostratigraphic data become available, for example, those from ANDRILL (e.g., [Scherer et al., 2007](#); [Winter et al., 2010](#)) and those anticipated for IODP Expedition 318 to the Wilkes Land Margin, East Antarctica (e.g., [Expedition 318 Scientists, 2010](#)).

Nonmarine Antarctic Waters: Freshwater Diatoms

Less than 1% of the Antarctic continent is ice free and here diatoms can grow in lakes and streams as well as in terrestrial habitats. The majority of the lakes are situated on the coastal oases (e.g., McMurdo Dry Valleys, Vestfold Hills, Larsemann Hills, and Schirmacher Oasis), the ice-free areas of the Antarctic Peninsula (e.g., James Ross Island, King George Island, and Livingston Island) and the Antarctic Islands (e.g., Signy Island). Modern ecological and distributional data have been collected

Figure 9 Composite range chart of 116 diatom taxa showing the total ranges (dark gray) and the average ranges (light gray). Each range end is plotted at the midpoint of its best-fit interval (see Cody et al., 2008). Data are presented in Table 3 of Cody et al. (2008). Reprinted from Cody RD, Levy RH, Harwood DM, and Sadler PM (2008) Thinking outside the zone: High-resolution quantitative diatom biochronology for the Antarctic Neogene. *Palaeogeography, Palaeoclimatology, Palaeoecology* 260: 92–121. Copyright (2008), with permission from Elsevier.

from several areas; for reviews see Jones (1996), van de Vijver and Beyens (1999), and Spaulding et al. (2010). The species diversity of nonmarine diatoms in Antarctica is low compared to Arctic regions, with few species in common, probably due to the physical isolation of the continent. The Antarctic Peninsula has a more diverse flora with a general trend of decreasing diversity southward (Jones, 1996). Many Antarctic diatoms are classed as aerophilic but are also found in aquatic habitats subject to desiccation or freezing; others are found in association with terrestrial soils and mosses. Some taxa are widespread whilst others have a regional distribution, and some are endemic (see Jones, 1996). Spaulding et al. (2010) review the ecology and distribution of diatoms in terrestrial and freshwater habitats from Antarctica and also provide more detailed information on Antarctic diatoms that have been used in environmental reconstruction.

Pre-Holocene records from Antarctica are rare but Hodgson et al. (2006) report a diatom record from marine isotope stage (MIS) 5e from East Antarctica. At this site, the diatoms from the last interglacial suggest a productive environment. The species are similar to those found in the subantarctic at present, and include species that are not found at present in east Antarctica. Hodgson et al. (2006) suggest a warm and wet interglacial environment consistent with the warmer temperatures shown by Antarctic ice cores.

Holocene stratigraphic records have accumulated in many lakes, and due to the low diversity of Antarctic freshwaters and the absence of many other proxies conventionally used in temperate regions (e.g., pollen), diatoms have been extensively used for environmental reconstruction. Hodgson et al. (2004) provide a recent review of Antarctic paleolimnology in general and Spaulding et al. (2010) review the uses of diatoms in particular. Diatoms have been used as indicators of climate and ecosystem change. They have also been used as indicators of salinity, which in some lakes can be a proxy for climate while in others it is related to changes in sea level. Diatoms have also been used as indicators of the changing extent of lake ice cover and lake depth.

Transfer functions have been developed for a range of environmental variables; for example, Jones and Juggins (1995) created a transfer function for nutrients (chlorophyll *a*) based on surface sediments obtained from Signy and Livingston Islands. This was applied to Holocene cores from Signy Island and, together with other proxy data, it showed a Holocene climate optimum between 3800 and 1300 ¹⁴C year BP (Jones et al., 2000) when the productivity of the lakes was higher. Recent changes in the diatom flora related to nutrient enrichment from birds and seals were also observed.

Transfer functions for salinity have been developed for diatom floras in the Vestfold and Larsemann Hills. The water chemistry of lakes in these areas responds quickly to changes in the moisture balance, with increasing salinity and decreasing lake water level during dry periods, and the opposite pattern in wet periods. Roberts et al. (2001) used a transfer function approach to obtain a high-resolution record of evaporation for the last 650 years from Ace Lake (Vestfold Hills), which was also highly correlated to the seasonal oxygen isotope signal preserved in an ice core from Law Dome, suggesting that the diatom-based reconstructions provide a robust paleoclimate signal.

The McMurdo Dry Valleys, located on the western coast of the Ross Sea, are amongst the coldest and driest places on Earth. Lakes here have some of the harshest aquatic environments in the world. The lakes mostly have a perennial ice cover (2.8–6 m thick) over liquid water. The volume of these lakes has fluctuated greatly over the last 20 000 years and, in recent times, lake levels have been rising. Lake Hoare is a perennially ice-covered, closed-basin lake where diatoms form part of the benthic microbial mats, with characteristic species occurring in shallow-water, mid-depth and deep-water communities (Spaulding et al., 1997). The lake has a unique sedimentary environment where, due to lack of water circulation, the sediments accumulate *in situ* and so record the history of a particular site rather than integrating events over the whole lake basin. Analysis of the sedimentary diatoms from Lake Hoare indicates that the rapid increase in lake level is a recent event (Spaulding et al., 1997).

Diatoms have also been found in Antarctic ice cores such as Dome C and Taylor Dome. These are a mixture of freshwater and marine taxa, which have been blown in by long-distance transport (Kellogg and Kellogg, 1996a). At Taylor Dome, Kellogg and Kellogg (1996b) found that low abundances of diatoms occur during glacial intervals (MIS 3–5), and higher abundances occur during interstadials (MIS 5b, 5d, and 6). This is due to the conditions in the source areas; in glacials, the West Antarctic Ice Sheet covers most of the Ross Sea continental shelf and thus the nearest open-water source for marine diatoms would be far offshore. The extent of ice-free areas in the dry valleys would also have been limited by lobes of grounded ice pushing into the valleys from the sea and by large ice-covered lakes greatly reducing possible sources for reworked marine diatoms (Kellogg and Kellogg, 1996b).

Freshwater Laminated Sequences

Introduction

Varves and Diatoms – Ideal Objects for Paleoecological Studies

Varved or annually laminated sediments contain high-precision records of sedimentation with yearly and even seasonal resolution (Lamoureux, 2001). Varves, especially in unconsolidated sediments, may be difficult to discern or may be easily disturbed by coring, so they are best sampled by freeze coring (Glew et al., 2001). Varve formation is a consequence of low-energy sedimentation, and it can therefore also indicate good preservation of various constituents of the sediment. A particular benefit of sediment varves is that they provide a precise chronology for the sediment sequence. The chronology may be floating or absolute (calendar), depending on the possibility to fix the series to the present day or any historical event, and more or less accurate, depending on the regularity and ease of identification of the annual cycles.

Diatoms are often abundant and are usually well preserved in lake sediments. Sedimentary diatom analysis is a versatile tool for tracking environmental and climatic history (e.g., Battarbee et al., 2001; Smol, 2004). Diatoms in varved sediments provide environmental records of very high quality, but the relative rarity of varved sediments sets limits on their routine use as environmental archives. In many cases, however, it is possible to improve the interpretation of nonvarved sediment records by comparisons with varved ones.

Friedrich Nipkow – Splendid Pioneer

Friedrich Nipkow (1886–1963) is worth remembering as an early pioneer of paleolimnology, and especially for his studies of diatom records in varved sediments. By profession a pharmacist, he studied algae as a hobby in his own laboratory in Zurich, Switzerland. He utilized a simple tube sampling device to collect profundal sediment cores from the deep lakes Zürichsee and Baldeggersee, which at that time were becoming strongly eutrophic from the input of untreated sewage effluents.

Nipkow (1927) presented excellent photographs of the varved sediment samples (Figure 1), as well as microphotographs of his diatom slides showing the seasonal assemblages and cell size variation observed within the varves. Varve formation had started in both the lakes a few decades earlier as a consequence of hypolimnetic anoxia. Nipkow convincingly verified the laminae as true varves by their seasonal diatom microstratigraphy and by correlation of species occurrences in the varves with previous plankton records. Furthermore, he could connect several turbidite layers observed in the sediments with historically known landslides on the lake shores.

Nipkow meticulously dissected each varve in his samples into 5–10 seasonal layers and analyzed the diatoms in each in great detail. Besides demonstrating the size reduction–auxosporulation cycle (a phase in the life cycle of diatoms in

which they form specialized reproductive cells) for several species (Figure 2), he also described year-to-year plankton community succession in both the lakes and discussed the potential effects of environmental conditions on the diatom development. There is also a good discussion about the advantages provided by the continuous and quantitative sediment records over the laborious long-term monitoring of plankton in water samples.

Diatoms as a Structural Component in Sediment Varves

The siliceous frustules of diatoms are a quantitatively important constituent in many lake sediments. Rapid and straightforward sedimentation of seasonal blooms of planktonic diatoms may result in distinct diatom-rich layers in the sediment. Often yellowish or greenish in color, these may be pure enough to be classified as diatomite. Such layers are often regular and visually significant structural elements in varves (Figure 3; Simola, 1992).

Often the annual character of rhythmically laminated sediment can be demonstrated by the microstratigraphy of diatoms, reflecting the regular yearly succession and the seasonal blooms of planktonic diatoms (Simola, 1992). In other cases, the absence of such seasonality may indicate a nonannual rhythmite.

Combining diatom microstratigraphy with other interannual or sublaminar sediment characteristics (facies units, their composition, and thickness) may allow detailed reconstruction of the typical seasonal patterns of catchment, and climate events and changes over time (e.g., Kienel et al., 2005; St Jacques et al., 2009). In very deep lakes, the highly variable settling rate of different types of sedimentary particles must be taken into account when looking at the composition of the varve subunits.

Methods of Analyzing Diatom Microstratigraphy

Numerous methods have been developed for studying diatom microstratigraphy, the choice depending on the objectives of the particular study. Basically, there are two approaches: (i) dissection of the sediment core into thin horizontal subsamples, in which the constitution of each separated layer can be studied individually, and (ii) preparing of vertical sections of the core, which enables the study of stratigraphic details in a single sample.

Nipkow (1927) was able to manually dissect varves in his fresh sediment cores into less than 1-mm increments and could estimate even the relative diatom frustule concentrations in these. Cocquyt and Israël (2004) described a microtome device allowing sediment subsampling optimally in 0.1-mm thick horizontal slices. These techniques are best suited for fairly compact sediments, for example, calcareous sediments.

Figure 1 Friedrich Nipkow's photographic documentation and interpretation of the varved sediment of Lake Zurich (Nipkow, 1927).

It may not be possible to reach similar precision with soft organic sediments, which may be better suited to freezing and freeze drying. Schmidt et al. (1995) described a suction sampler for fine-resolution subsampling of freeze-dried varves and their structural components.

An advantage of fine-resolution horizontal slicing is that the material can be properly treated for the preparation of high-quality diatom slides. Furthermore, sampling of a somewhat extended horizontal area (at least some square millimeters) helps overcome the problem of uneven distribution of diatom frustules in each individual layer. A drawback of this approach is, of course, that it is very laborious, especially when dealing with longer varve sequences.

The tape peeling technique (see Simola, 1992) is a simple method for obtaining vertical sediment sections for

microscopy. From the cleaned surface of a frozen and slightly freeze-dried sediment core, a thin layer of sediment particles is adhered on strips of adhesive tape. The tape strips can be directly mounted onto microscope slides with a suitable liquid mounting medium, for example, Canada balsam. Unmounted, such tape strips are also suitable for direct examination by scanning electron microscopy (SEM; Dean et al., 1999). For clean diatom slides of tape peels, Davidson (1988) transferred the sediment particles onto a microscope slide spread with rubber glue, which he then incinerated and mounted with diatom mounting medium.

A standard technique for making permanent thin sections of soft sediment samples involves replacement of the interstitial water via acetone into a low-viscosity epoxy that is polymerized into a solid and transparent matrix (Kemp et al., 2001), after which the samples are ground into thin slides, analogous to petrographic thin sections. As pointed out by Cocquyt and Israël (2004), identification and counting of long, spindle-shaped diatoms may be especially difficult in such thin sections.

Diatom Assemblages Provide High-Resolution Records of Environmental Changes

Human Impact and its Relaxation

Ever since Nipkow (1927), a large number of paleolimnological varve studies have detailed the eutrophication and pollution history of lakes caused by human influence (for a general summary, see Hall and Smol, 2010). In many cases, eutrophication, leading to hypolimnetic anoxia, has actually triggered the onset of varve formation in the sediment.

The early studies were mainly based on empirical knowledge of the significance of individual taxa in diatom communities as indicators of water conditions such as trophic status, saprobity (the physiological and biochemical characteristics of an organism that permit it to live in water that is somewhat polluted), or pH of water bodies. The accumulated knowledge of diatoms as indicators of pH proved invaluable, when acid rain was recognized as a widespread and serious environmental problem in the 1980s (Hall and Smol, 2010). The modern approach to diatom-based environmental reconstruction typically involves a calibration data set of at least some tens of lakes, by which statistical transfer functions between species assemblages and the relevant environmental parameters are worked out. The transfer functions are then applied to make paleoecological inferences.

As a positive sign, increasing numbers of recent studies have been able to demonstrate aquatic ecosystem recovery from the effects of eutrophication or acidification. Alefs and Müller (1999) identified a four-phase eutrophication succession of sedimentary diatom assemblages within the varved sediments of two prealpine lakes in South Germany. The plankton diatom assemblages appear rather similar in both lakes, but varve dating reveals temporal differences in the onset, progress, and relaxation of the eutrophy between the lakes. This study topic will gain even more importance in the near future, when the enforcement of active water protection policies (e.g., The EU Water Framework Directive) will require knowledge of the natural or predisturbance status of impacted water bodies.

Größenwechsel der sedimentierten Planktondiatomeen im geschichteten Tiefenschlamm des Zürichsees aus dem Zeitraum 1896—1924

Figure 2 Nipkow's graph of yearly size distributions in the populations of major plankton diatoms in the varved sediment of Lake Zurich (Nipkow, 1927). Note that the time-scale on the vertical axis is inverted, so that the oldest varve (1896) is at the top and the last (1914) at the bottom. For each varve, one or two size distributions have been determined from individually dissected seasonal layers for each of the six planktonic taxa presented. The horizontal scales mark the measured size for each taxon: frustule length for the araphids (*Fragilaria crotonensis*, *Tabellaria fenestrata*, *Synedra delicatissima*, and *Asterionella gracillima*), and diameter for the centrics (*Melosira islandica* and *Stephanodiscus hantzschii*). Cycles of abrupt cell size increase and subsequent gradual decrease are evident in all the populations.

Figure 3 A tape peel of sediment varves of Lake Laukunlampi, East Finland. The varves are delimited by the dark brown humus-rich winter layers; each varve contains one or more light-colored diatom-rich strata. The photographed sequence spans the period 1964–1981; scale in cm.

The baseline conditions need to be known so as to obtain a realistic goal for the management or restoration measures, and advanced paleolimnology is often the sole provider of this information (e.g., Flower et al., 1997; Miettinen et al., 2005).

Geological Processes and Catchment Events

In suitable cases, the study of long varve series will allow precise dating and high-resolution diatom analyses to assess lake ecosystem dynamics on geological time scales. Long varve series are, in fact, fairly commonly found in the early postglacial sediments on northern European lakes (e.g., Ralska-Jasiewiczowa et al., 1998). Unfortunately, however, these varve records seldom extend to the present day. Typically, they provide floating chronologies for the gradual oligotrophication (decline in the level of nutrients) of the water bodies as a consequence of catchment evolution since the end of the last glaciation through processes of landscape, vegetation, and soil development. Gradual filling in of the basin and declining productivity may have led to weakened stratification and lessened anoxic tendencies, and thus eventual cessation of varve deposition in the typical development of such lakes.

Coastal meromictic lakes are a special category of basins with a high tendency for varve formation. Especially in areas of isostatic land uplift, such as the Baltic coasts in Northern Europe, and northeastern North America, there are numerous recently isolated coastal lakes, with residual or recurring salt water-induced meromixis (lack of mixing of water layers

in a lake). The diatom records in the sediments of such lakes may, of course, reveal and date the isolation process itself with great accuracy, but particularly in the arctic areas, they may also serve exceptionally well as archives of catchment development and climatic events, as demonstrated by the multidisciplinary Taconite Inlet Lakes Project (Douglas et al., 1996).

Inferring Past Climatic Changes

Much recent research has been focused on tracking the climatic signal in sedimentary diatom records. There is plenty of evidence that diatoms are indeed sensitive indicators of climatic factors, either directly or indirectly, in different climatic zones (Battarbee et al., 2001). Even here, varved sequences are of great value; besides serving as a dating tool, they even provide a record of seasonal patterns and year-to-year variability of the sedimentation process. Detailed analysis of currently depositing varve series may enable verification of the climate signal through correlations with instrumental records (e.g., Blass et al., 2007; Boes and Fagel, 2008; Lamoureux, 1999; St Jacques et al., 2009).

Overall, the main problem is to distinguish the specific climatic signals from those of catchment processes and especially from human disturbance, which has a long, variable, and often poorly documented history in most lake catchments of the world (e.g., Kienel et al., 2005; Lotter and Birks, 1997).

The climate signal appears fairly straightforward in some arctic varved lakes, in which the annual diatom production and sedimentation is typically associated with the length of the ice-free period, hence, summer temperature, and varve thickness often records snowmelt runoff, or winter snow quantity (Douglas et al., 1996; Lamoureux, 1999). In lower latitude climate zones, such relationships tend to be more complicated, but some similar patterns may be discerned. Thus, in regularly freezing dimictic lakes (lakes that mix from top to bottom twice per year), abundant spring diatoms appear to indicate a warm spring with an early ice break-up and prolonged water circulation, whereas copious winter snow would be likewise reflected in a thick minerogenic spring flood layer (e.g., Baier et al., 2004; Ojala et al., 2008). There is plenty of random variation, however, as shown by Gälman et al. (2006) in a comparison of three varve series deposited in close proximity to each other and in very similar conditions (two separate basins in one lake and one in a nearby lake), representing the late twentieth century. Even though the varve series could be correlated year by year, there was still great variance in the thickness and constitution of individual varves representing the same year.

St Jacques et al. (2009) made use of the seasonal occurrence of diatoms within varves to interpret seasonal climate patterns in a 900-year varved sequence in a lake in Minnesota, USA. They determined the relative abundances of sedimentary diatom taxa and chrysophyte scales in the dark (winter-spring) and light (summer) laminae of short sequences of typical varves, and combined this algal seasonality with pollen-inferred temperatures and other proxy data for the sequence. They found inferences for two separate limnological features, namely for the intensity of spring mixing (characterized by the abundance of *Stephanodiscus minutulus*, indicating mild winters, early ice out), and for the severity of summer stratification

(e.g., *Cyclotella pseudostelligera* and low diatom:chrysophyte scale index; indicating summer epilimnetic nutrient depletion). The varying patterns of spring mixing and summer stratification, reflecting the essentially unrelated winter and summer weather conditions, also explain the seasonal variations in nutrient levels, which may appear confusing when inferred from nonseasonally analyzed diatom assemblages.

Avenues for Further Research

Species-Level Studies of Diatoms in Sedimentary Records

The current paleoecological assessments are mainly based on community-level analysis. Inferences are drawn of observed correlations between environmental parameters and gross diatom assemblages. The ecological inference potential could be further refined by incorporation of species-level autecological information into the models. Basic algological research is still needed, especially concerning planktonic taxa and the factors affecting their population dynamics, that is, species responses to seasonal limnological events. Actual monitoring of lakes with ongoing varve deposition, combined with follow-up analysis of the sediment record, has great potential in providing this kind of improved ecological understanding of single species and of typical assemblages (Köster and Pienitz, 2006).

Detailed studies of single-species dynamics within varved sediments could, in turn, serve basic algological and ecological research. Research questions, partly outlined already by Nipkow (1927), include diatom cell-cycle dynamics (size reduction–auxosporulation cycles and their timing); within-population morphology variation; and possible genetic studies in sediments with well-preserved diatom cells. Such studies could lead to a better understanding of the species concept, especially for common taxa with diffuse and difficult species identification (e.g., *Aulacoseira*, *Stephanodiscus*).

Simola et al. (1990) is an example of microstratigraphic diatom analysis conducted with a primary aim to study the population dynamics and species interactions of planktonic taxa. This study of a 418-year long regularly varved sequence provided data on the seasonality and year-to-year dynamics of the analyzed taxa, but, unavoidably, detailed interpretation of the results was hampered by the lack of corresponding environmental data (as an aside, the 418-year population histories of some plankton diatoms presented in this article have ended up in a biostatistics textbook as typical examples of ‘chaotic’ time series).

Revisiting Well-Documented Varves for a Better Understanding of Postdepositional Processes

Taphonomic processes, or the numerous factors and events that tend to alter the representativity of a fossil assemblage in comparison with the original living communities, are a major issue in paleoecological reconstructions. However, this is rarely accounted for in routine analyses, which usually take the analyzed assemblages at their face value.

Postdepositional dissolution is a very significant factor shaping the fossil assemblages or indeed completely destroying diatom frustules in sediment deposits (see **Large Lakes**

Figure 2). Experimental studies (e.g., Battarbee et al., 2001; Flower, 1993) have demonstrated quite dramatically that the species composition of a fossil assemblage may show very little resemblance to the original one, if only a few robust forms remain while all the common ones have dissolved. In extreme cases, the remaining fossil assemblage may even be dominated by taxa that, owing to their initial rarity, would not have been recorded in the analysis of the original sample. Dissolution is exemplified by the common plankton diatoms *Urosolenia* and *Attheya*, which are hardly ever included in calibration data sets, because their very thin frustules are rarely encountered in lake sediments (their cysts may be observed, but usually not in abundance).

Revisiting well-documented varve deposits would provide very useful information for the typical postdepositional dissolution process, particularly its duration and timing, and the way it affects different species in different types of sediments. This kind of information could considerably improve the interpretation accuracy and potential in paleoecological inference studies.

Large Lakes

A W Mackay, University College London, London, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Large lakes are generally defined as those with a surface area of over 500 km² (Tilzer and Serruya, 1990). They are irregularly spread out across the globe and contain over 90% of global surface freshwater resources (Herdendorf, 1982). However, perhaps a more reliable metric of a large lake is the volume of water it contains, as significant changes to surface area can occur if the lake is shallow and hydrological inputs alter. For example, extraction of water for irrigation in central Asia has resulted in the Aral Sea losing 75% of its surface area and 90% of its volume in recent decades, and the lake now exists as several separate water bodies (Micklin, 2007). The 20 largest lakes (by volume of water) are summarized in Table 1 and their geographical position is shown in Figure 1. Half of these lakes are tectonic in origin while the other half were formed from glacial activity. These lakes show some specific geographical distributions, which have important implications for Quaternary reconstructions using diatoms and other proxies. For example, all but one of the large, glacial, ice-scour lakes are found in North America north of 40° N latitude between young sedimentary strata and more northerly Precambrian shield rocks (the remaining glacial scour lake is Lake Ladoga in western Russia). Moreover, only one large lake (Hamoun i Helmand) is found between 20° N and 40° N, mainly because aridity prevents their development between these latitudes.

By definition, large glacial lakes contain only sedimentary diatom deposits formed since deglaciation, and records, therefore, commonly span less than 20 ka BP. Longer records are therefore best extracted from either extant lakes with deep basins in active rift zones, or paleolakes that have since in-filled or dried up, but the presence of which once spanned the Quaternary. The long sedimentary records of tectonic lakes are being increasingly exploited. Quaternary diatom studies are most advanced from Lake Baikal, due to the Baikal Drilling Programme (BDP), which began extracting long records in the early 1990s (Williams et al., 2001). However, under the auspices of the Intercontinental Drilling Program (<http://www.icdp-online.de>), other large lakes in tectonic basins have recently been cored, for example, Lake Titicaca in 2001 and Lake Malawi in 2005, and plans are underway for future coring expeditions, for instance in Lake Issyk-Kul.

Diatoms as Paleoenviromental Proxies

Interpretation of the climate record held by diatom proxies in the sediments of large lakes is enhanced in cases where there is knowledge of population growth and succession in the water column, and an understanding of how diatoms are transported to the sediment surface and ultimately incorporated into the sedimentary record (Mackay et al., 2003). In this respect, the quality of diatom preservation can be assessed and key,

controlling climatic variables evaluated. Diatom-inferred climatic interpretations therefore require knowledge of taphonomic processes, most notably dissolution (Ryves et al., 2001), which can be used to improve paleoenvironmental reconstructions (Ryves et al., 2009).

The types of diatom communities that can be found in large lakes depend on lake morphology (i.e., is the lake deep or shallow?), age of the lake, and prevailing climate. For example, the sensitivity of large lakes to changing water balance can often be reflected through the ratio of benthic to planktonic diatoms. In Lake Titicaca, high abundances of benthic taxa (often approaching 100%) are indicative of shallow closed-basin conditions during periods of reduced regional glaciation (Fritz et al., 2007). During periods of increased glacial extent around Lake Titicaca, water balance is much higher, the lake water is fresh, and planktonic diatoms dominate sedimentary assemblages (often >80%; *ibid.*). Planktonic diatoms in large, deep lakes may also be adapted to other hydrological processes different from those in large, shallow lakes such as increased time spent out of the photic zone due to deep-water mixing (e.g., in Lake Baikal), or the importance of internal cycling over external inflows on nutrient budgets over short timescales (e.g., in Lake Victoria; Tilzer, 1990).

Large tectonic lakes are undoubtedly some of the world's oldest water bodies, and this great age tends to result in planktonic diatom assemblages with low diversity, especially in comparison to large, glacially formed lakes, which can contain species assemblages representing many planktonic genera (Stoermer and Edlund, 1999). Attempts to explain low plankton diversity in lakes such as Lake Baikal include competitive exclusion (e.g., Stoermer and Edlund, 1999) and resource gradient and competition theory (Edlund, 2006).

Case Studies

The range of diatom-based paleolimnological studies is vast; however, these studies cover mostly Late Glacial–Holocene periods. There are rather few diatom records from large lakes covering the whole of the Quaternary, in comparison to marine records. Four case studies are considered here because they represent ongoing challenges in the field of paleoclimatology/paleolimnology over the Quaternary. Case study 1 is from Lake Baikal in Russia, situated within an active tectonic region of the Eurasian plate (51°28′–55°47′N and 103°43′–109°58′E; Figure 1). Quaternary diatom records, associated trends in biogenic silica (BioSi), and $\delta^{18}\text{O}$ analysis of diatom silica (e.g., Mackay et al., 2011) from this lake have greatly increased our understanding of climate variability in continental regions far from oceanic influences, hence the comprehensive treatment of this lake here. Case study 2 is from Lake Titicaca, which lies between Bolivia and Peru in South America (15°45′S 69°30′W; Figure 1). This lake is found to the north

of the Altiplano of Peru, the world's second highest plateau (after Tibet), and as such Lake Titicaca is the highest large lake in the world. Paleoclimate records for this site are available for much of the late Quaternary period. The third case study uses diatom records from one of the world's largest tropical lakes, Lake Victoria in Africa (01°00' S 33°00' E; [Figure 1](#)), bordered by Kenya, Tanzania, and Uganda. Lake Victoria is relatively shallow, and observations in the 1960s revealed that the lake had dried out completely toward the end of the last glacial ([Kendall, 1969](#)). It was this observation that challenged conventional orthodoxy at the time, which held that tropical regions experienced wetter climates during the Late Glacial. Although there has been much debate since then on the extent and timing of this desiccation event, recent work indicates that it occurred between approximately 15.9 and 14.2 cal ka BP ([Stager et al., 2002](#)). The final case study focuses on sediments recently extracted from Lake Malawi ([Figure 1](#); spanning approximately the last 144 ka) as part of the IDP 2005 programme ([Stone et al., 2010](#)). Lake Malawi (9–14° S) is of

tectonic origin, and is the world's fifth largest lake ([Table 1](#)). It is bordered by Malawi, Mozambique, and Tanzania, and is the southernmost of the East African Great Lakes.

Lake Baikal

Lake Baikal, situated in southeast Siberia ([Figure 1](#)) has long been recognized as one of the world's most unusual freshwater ecosystems, especially in terms of its age (in excess of 20 Myr), depth (~1640 m) and volume (23 600 km³), its uninterrupted sedimentary record and the high degree of endemism that exists within the lake. Another important feature that sets Lake Baikal apart from other large, deep lakes is that its entire water column is saturated throughout with oxygen, due to regular renewal of the deep waters every spring and autumn. This results in the oxidation of even the deepest bottom waters, allowing an extensive and almost wholly endemic deep-water fauna to survive.

Figure 1 Map showing the distribution of the world's 20 most voluminous lakes. The numbers given correspond to the ranking of the lakes, as indicated in Table 1.

Diatoms are important primary producers and are crucial to the ecosystem functioning of Lake Baikal (Popovskaya, 2000). The most common planktonic diatoms in Lake Baikal are a mixture of endemic taxa (e.g., *Aulacoseira baicalensis*, *Cyclotella minuta*, and *Stephanodiscus meyerii*) and cosmopolitan taxa (e.g., *Synedra acus* and its varieties, and *Nitzschia acicularis*). The distribution of Lake Baikal diatoms exhibits significant spatial variability across the lake, dependant on a number of factors including climate (e.g., ice and snow cover) and hydrological factors such as water depth and fluvial input (Mackay et al., 2006). As much as 40% of the lake's diatoms may be endemic although this figure is being revised upward as more comprehensive studies in deeper littoral zones (>20 m) are carried out (Flower, 2005) and centers of hyperendemicity become recognized around the lake. The diatom assemblages in Lake Baikal contain several examples of species flocks, and relict distributions of previously more widespread taxa (ibid.). Genkal and Bonderenko (2006) further proposed that many of the common endemic planktonic diatoms found in Lake Baikal today should be reclassified as relicts because they are morphologically very similar to neighboring mountain lake species.

The paleoclimatic archive of Lake Baikal sediments is of global importance, given its position in one of the most continental regions of the world where continuous, high-resolution records spanning the Quaternary are otherwise sparse. Lake Baikal diatoms and associated BioSi have proved

to be extremely useful paleoclimate proxies, in part because of the intense seasonality of the region, and also because of the size of the lake, which covers 4° latitude, across which a distinct climatic gradient exists. Given the depth and volume of Lake Baikal, it is important to assess factors that may affect diatom integrity before their final incorporation in the sedimentary record.

As in the marine environment, the entire water column of Lake Baikal is undersaturated with respect to silica (Falkner et al., 1991), and therefore diatom valve dissolution has always been an important process through glacial and interglacial cycles. In a study comparing recent diatom fluxes through the water column with fluxes being incorporated into the sediments, Ryves et al. (2003) demonstrated that in the south basin of Lake Baikal, only ~1% of the valves are preserved in the sedimentary record. Once incorporated into the sediments, dissolution of diatom silica continues into the pore waters, until saturation of pore waters by Si is reached, thereby limiting further dissolution. During glacial periods, few diatoms were preserved in the sedimentary record. This is most likely due to more intense relative dissolution processes operating on fewer diatom cells growing during colder climates (Carter and Colman, 1994; Mackay, 2007; Swann and Mackay, 2006).

Although the impact of dissolution on the diatom records from Lake Baikal has been recognized since some of the earliest studies, only recently have the quantitative impacts been

determined (Battarbee et al., 2005; Mackay et al., 2005; Ryves et al., 2003). Dissolution is problematic from a paleoenvironmental perspective because partially dissolved valves are often difficult to identify – see Figure 2. Furthermore, assemblages may be biased toward more robust, heavily silicified species, thus influencing paleoclimatological reconstructions, or more seriously, taxa may be removed from the record altogether.

One of the first studies to relate changes in Lake Baikal diatom composition to changes in orbital forcing was by Grachev et al. (1998) who worked on BDP cores extracted from the Academician Ridge. They highlighted the observation that relatively few planktonic taxa tended to dominate the sedimentary assemblages during interglacials. Moreover, they also noted the successional nature of the changing flora, especially during approximately the last 1 Myr, as diatom abundances suggested progressively longer, more severe glaciations, with different species perhaps dominating the record at different stages for less than 1 ka. Notably, although many of these taxa are now extinct, several of these diatom assemblages include species commonly found in the lake today, such as *C. minuta*, *A. baicalensis*, and *Aulacoseira skvortzowii*.

However, the most detailed study on diatom species responses to orbital forcing indicates that over the last 0.8 Myr (since the onset of the mid-Pleistocene revolution) 31 local diatom assemblage zones can be characterized, corresponding to MIS 1–19 (Khursevich et al., 2001; Figure 3). This study is important because Khursevich et al., make the link between diatom evolution and insolation changes, thereby adding to the debate on evolutionary pressures on relatively short time-scales. More specifically, species responses varied depending

Figure 2 Dissolved and near pristine images of two endemic, planktonic diatoms found in Lake Baikal sediments. Images (a) and (b) are dissolved valves of *C. gracilis* and *C. minuta*, respectively, found in a marine isotope stage (MIS) 3 sequence extracted from the north basin of Lake Baikal. Images (c) and (d) are of pristine valves of the same species, this time found in the MIS 5e sequence of the same core. Photographs courtesy of George Swann and Patrick Rioual.

on whether insolation amplitude was small (e.g., as occurred between MIS 15a and 11, corresponding to the almost continuous presence of *Stephanodiscus flabellatus* var. *distinctus* Khursevich and its varieties) or large (e.g., as occurred between MIS 19 and 15e, during which time each precessional cycle was dominated by a different species, which subsequently became extinct). Furthermore, during the last 0.8 Myr, there were also apparent differential speciation rates between the genera, with 16 new species of *Stephanodiscus* being recorded in comparison to only four for *Cyclotella* (Khursevich et al., 2000, 2001). Importantly, during this time, ice volume increased during each subsequent glaciation, indicative of prolonged glacial periods. Such diatom responses to climate during the Pleistocene have not been witnessed in any other freshwater or marine environment (Khursevich et al., 2001). Detailed records also exist for changes in diatom assemblage composition prior to the last 0.8 Myr, with the onset of Northern Hemisphere Glaciation influencing extinctions in at least two genera in the

Figure 3 Biostratigraphic position of major diatom species plotted against a biogenic silica record over the entire Quaternary in Lake Baikal. Redrawn from Khursevich GK, Karabanov EB, Williams DF, Kuzmin MI, and Prokopenko AA (2000) Evolution of freshwater centric diatoms within the Baikal rift zone during the late Cenozoic. In: Minoura K (ed.) *Lake Baikal: A Mirror in Time and Space for Understanding Global Change Processes*, pp. 146–154. Amsterdam: Elsevier.

lake toward the beginning of the Quaternary. Following this time, endemic *Cyclotella* species developed and dominated the diatom flora, including *C. praetemperei*, until approximately 1.7 Myr, followed by *C. comtaeformica* up to approximately 1.25 Myr (Khursevich et al., 2000).

Lake Titicaca

Lake Titicaca was formed by tectonic activity approximately 3 Myr ago. This large, monomictic lake is an important site for Quaternary studies because (i) it is the only large, deep, freshwater lake in South America; (ii) the lake itself is sensitive to changes in precipitation (Tapia et al., 2003); and (iii) its sedimentary archive extends back through many glacial-interglacial cycles (Fritz et al., 2007), and hence offers the possibility of high-resolution paleoclimate reconstructions in this understudied region of the globe (Baker et al., 2001).

Detailed diatom analyses of late Quaternary sediments from Lake Titicaca have contributed significantly to the debate on tropical precipitation trends since the last glaciation, especially within the Amazon Basin. In general terms, diatom-based reconstructions have demonstrated that during the Late Glacial period, the climate over the Altiplano was wet, whereas a significant shift to a more prevalent drier climate occurred during the early to middle Holocene (Baker et al., 2001).

Although these scenarios are based on qualitative interpretations of diatom communities present in the lake, they are robust because they are confirmed by other proxies found in the sediment archive (e.g., Cross et al., 2000). Initially, Baker et al. (2001) grouped diatoms according to their preferred habitat of living in the planktonic or littoral regions of the lake. High proportions of sedimentary benthic or littoral taxa were therefore attributed to prevailing arid climates resulting in lower lake levels. Conversely, high proportions of planktonic taxa were indicative of higher lake levels (increased lake volume) due to prevailing wetter climates. High lake levels in Lake Titicaca and wet Amazonian conditions correspond today to

cold, northern equatorial Atlantic sea-surface temperatures. On this basis, changing diatom assemblages highlight that Lake Titicaca has been sensitive to changes in the North Atlantic thermohaline circulation during both the Younger Dryas and even Bond cycles through the Holocene (Baker et al., 2001).

Tapia et al. (2003) considered these diatom responses in more detail. Periods of deep water in the lake, indicative of wetter climate, were characterized by planktonic diatoms, especially the *Cyclotella stelligera* complex between 30 and 24 ka BP and *Cyclotella andina* throughout the Late Glacial period up to approximately 8 ka BP. Two further diatom groups were recognized in the sedimentary profiles: saline indifferent taxa, especially *Cyclotella meneghiniana*, which has a very wide tolerance to varying lake salinities, and saline taxa including *Chaetoceros muelleri*, which is indicative of low lake levels and corresponding paleoclimate aridity.

Using these groups, a paleoclimatic synthesis was developed (Tapia et al., 2003; Figure 4). Between 26 and 12.5 ka BP, freshwater planktonic taxa (mainly *C. andina* and *C. stelligera*) dominated, suggesting that lake levels were high and prevailing climate was therefore wetter, especially during the period coincident with the Younger Dryas in the Northern Hemisphere. High lake levels were interrupted by a period of aridity causing a decline in lake water volume during the transition from the Late Glacial into the early Holocene (as characterized by an increase in benthic taxa). However, this arid period was short lived, as planktonic diatoms again dominated the lake between approximately 10 and 8 ka BP, indicating that high lake-level stands can be compared to the wet Coipasa event in the central Altiplano (Sylvestre et al., 1999). The shift to prevailing drier climate during the early to mid-Holocene (as suggested by Baker et al. (2001) above) is characterized by marked increases in benthic taxa and *C. meneghiniana*, suggesting that a decline in lake level was accompanied by small increases in salinity. This lake-level decline culminated in the appearance of saline taxa for the first time in Lake Titicaca (*C. muelleri*) from 6 to 3.5 ka BP. However, low lake-level stands were temporary, and from approximately

Figure 4 Changes in diatom abundance for the past 31.5 ka BP in Lake Titicaca. Diatom groups represent the four ecological groups highlighted in the text. Gaps in the stratigraphy are zones barren of diatom valves or where diatom concentrations were too low to generate an accurate diatom count. Note that core NE97-7PC does not extend beyond 21 ka BP, while core NE97-5PC does not extend through the Holocene period. Reproduced from Tapia PM, Fritz SC, Baker PA, Seltzer GO, and Dunbar RB (2003) A late Quaternary diatom record of tropical climatic history from Lake Titicaca (Peru and Bolivia). *Palaeogeography, Palaeoclimatology, Palaeoecology* 194: 139–164.

4 cal ka BP, freshwater planktonic taxa began to grow and then dominate the flora again.

In 2001, new overlapping drill cores of ~136 m were extracted from Lake Titicaca as part of the GLAD-800 coring system. These sediments span approximately the last 370 ka (Fritz et al., 2007), and again diatom species were grouped as above (i.e., freshwater plankton, saline plankton, saline indifferent, and benthic species). Periods of positive water balance are characterized by high abundances of freshwater diatoms and low abundances of benthic taxa. These periods coincide with increased glacial extent, linked to higher rainfall and lower temperatures (Fritz et al., 2007). Low lake levels in Titicaca were inferred during MIS 5e, due to high abundances of the saline species *C. muelleri* – it is likely that the lake was a closed system at this time, influenced by the prevailing warm and dry conditions.

Lake Victoria

Lake Victoria was also formed by tectonic activity. Although Lake Victoria has an outlet into the Nile River, this accounts for only ~10% of water loss from the lake each year; the remaining ~90% is lost through evaporative processes. Lake Victoria is relatively shallow, with a mean water depth of ~40 m, and consequently small fluctuations in precipitation have marked effects on the lake's hydrology. Lake Victoria is monomictic and overturn occurs during the dry months of June–September, driven by the trade winds. This overturn period determines nutrient availability in the lake and is therefore crucial in controlling algal productivity, allowing diatom populations (including *Aulacoseira* spp. and *Stephanodiscus* spp.) to thrive in the lake. In recent years, however, primary production is increasingly determined by other algal groups, including diatoms indicative of more stable water conditions (e.g., *Nitzschia* spp.) and cyanobacteria (Hecky, 1993; Verschuren et al., 2002). Recent diatom analyses suggests that eutrophication in Lake Victoria is spatially complex and time transgressive, and may be related to longer term nutrient enrichment and climate instability (Stager et al., 2009).

Throughout the Late Glacial–Holocene period, Lake Victoria has been shown to be a sensitive recorder of climate variability because its hydrological regime is mainly controlled by precipitation/evaporation. Paleoenvironmental interpretations are based on the knowledge of the ecologies of different diatom taxa. For example, *Aulacoseira* species (e.g., *A. granulata*) are generally heavily silicified, and they therefore require considerable turbulence in the water column to keep their valves suspended in the photic zone. *Nitzschia* species (e.g., *N. acicularis*), on the other hand, are often more lightly silicified and have a large surface-area-to-volume ratio, which allows them to remain buoyant in more stable water conditions. Finally, benthic taxa, including *Fragilaria* species, are again indicative of shallow-water conditions, and when their numbers increase in lake sediment archives, this is often indicative of declining lake levels. Using these characteristics, diatom-inferred arid phases in this region of tropical Africa are coincident with weakening of Afro-Asian monsoon systems, linked to changes in North Atlantic thermohaline circulation associated with such phenomena as Heinrich events and meltwater pulses.

One of the best high-resolution records of Late Glacial diatom-inferred climate changes clearly demonstrates that

water levels in Lake Victoria were much lower during the Younger Dryas than at the start of the Holocene (Figure 5; Stager et al., 2002). Relative lake level is inferred from correspondence analysis axis-2 diatom sample scores from a core taken in the Damba Channel in the north of Lake Victoria. Stager et al. (1997) suggest that these benthic assemblages (consisting of taxa such as *Fragilaria* spp.) are indicative of lake depth. Periodicities in the diatom record from Lake Victoria are further interpreted as being indicative of Dansgaard–Oeschger cycles operating on precipitation trends in tropical Africa (Stager et al., 1997).

Further research exploiting Lake Victoria diatoms has reconstructed past change at very high resolution (1–6 years) for the last 1 ka. Diatoms were once again used to infer past changes in lake level, but a diatom-inferred conductivity model was also developed and applied to a 2-m core with a robust chronology (Stager et al., 2005; Figure 6). Increases in diatom-inferred lake-level changes over the last millennium were coincident with declines in solar activity, especially during the period commonly referred to as the Little Ice Age. Although solar fluctuations on these timescales are low in amplitude, the authors suggest that when insolation is reduced, cloud cover is increased, resulting in a decrease in evaporation from Lake Victoria. However, in the last 200 years, higher lake levels are positively associated with increased sunspot numbers, and so interactions are complex

and undoubtedly confounded by changes in thermohaline circulation in both the Atlantic and Pacific oceans.

Lake Malawi

Lake Malawi has a very seasonal climate: summers (December–April) are warm and wet, and are influenced by the southward migration of the intertropical convergence zone (ITCZ). Winters on the other hand (May–August) are much cooler and drier because the ITCZ migrates north toward the equator. Although Lake Malawi has an outlet (the Shire River in the southern basin), over 80% of water is lost through evaporation (Spigel and Coulter, 1996). Moreover, although Lake Malawi is fed by six major inflows, over 60% of hydrological input is from rain, which falls directly on the surface of the lake (Spigel and Coulter, 1996). Currently, anoxic conditions prevail below a water depth of ~230 m, which results in a sedimentary archive that sensitively records changes in the lake's hydrological balance (Stone et al., 2010). During winter, diatoms can comprise the majority of phytoplankton in Lake Malawi, but for the rest of the year, nutrients in surface waters are low, leading to low levels of diatom production (ibid.).

The longest diatom record obtained for Lake Malawi (as part of the Lake Malawi Scientific Drilling Project) spans the interval from approximately 144 ka to the onset of the

Holocene. However, many species in the early sediment record are not found in the lake today. Interpretation of past assemblages therefore takes account of diatom life strategies in the open water (e.g., euplankton, meroplankton, and tychoplankton) and known ecologies of dominant groups (e.g., if species are stephanodiscoid or cyclotelloid) (Stone et al., 2010). Principal components analysis (PCA) of major diatom groups (along with other biological and mineral proxies) clearly demonstrates a water-depth gradient along the first axis, reflecting lake-level changes of many hundreds of meters. During the early part of the record, prior to 70 ka, proxy evidence suggests that Lake Malawi was often more shallow and better mixed than it is today. For example, between 133 and 125 ka, the diatom assemblage was dominated by diatom species tolerant of saline lake water, for example, *Cyclotella* compare with *quirlensis*, while between 109 and 97 ka, shallow-water *Aulacoseira* species dominate assemblages (*A. ambigua*) together with abundant ostracods, indicative of a very shallow lake with complete ventilation of the water column (Stone et al., 2010). Greater variability in lake level prior to 70 ka occurred at a time when precessional forcing was strong due to high eccentricity. Post 70 ka, Lake Malawi was consistently deep, apart from two abrupt lowstands between approximately 64–62 and 47–30 ka, which were marked by, among others, shallow-water *Aulacoseira* spp in high abundance.

Conclusion

The case studies highlighted here indicate that diatoms make powerful proxies of past environmental change over the Quaternary period. For large lakes, by far the majority of the studies are focused on Late Glacial–Holocene changes. This is in part because half of the world's 20 largest lakes are glacial in origin and all but one of these lie in North America. Paleoenvironmental interpretations based on diatoms can be made using both qualitative aspects of diatom autecologies (e.g., habitat preference, morphology) and quantitative inferences, including the use of transfer function methodologies. In the field of paleoclimatology, increasingly sophisticated questions are being asked with respect to the magnitude of climate variability over different timescales and across different regions of the world. High-resolution diatom analyses from large lakes are now considered one of the most robust and useful tools in the field of Quaternary research.

Introduction

Historical Perspective

The study of seasonally laminated sediments from the geological record was brought to the fore by Gerard De Geer in the early twentieth century (De Geer, 1912). He introduced the term 'varve' to describe an annually repetitive sediment deposit within Swedish glacial marine clays. These late Quaternary varves comprise a silt-rich lamination, related to higher energy spring glacier melt, and a clay-rich lamination, related to lower energy in-wash and biological productivity in the summer. The description of these varves and the seasonal-scale proxy data that they contained, together with the realization that packages of varves could be correlated over tens of kilometers, demonstrated, for the first time, that an annual-scale chronology was possible and led to the first such chronology for the past 12 ka being erected in Scandinavia (De Geer, 1912). However, after De Geer's work, the study of laminated sediments, varves, and seasonal-scale proxy records was slow to progress. The geological community was skeptical about whether annual resolution was possible from the geological record. In the 1960s, Roger Anderson and his colleagues revived research into laminated sediment records (e.g., Anderson and Kirkland, 1960) and re-established the credibility of varves as proxy climate archives with the highest resolution.

In the marine realm, research was hampered until the 1970s by the technological challenge of recovering long sediment cores from the sea floor. However, early workers first recovered short cores of diatom-rich, marine laminated sediments from the Gulf of California, NW Mexico (Figure 1), and interpreted these as marine varves (Calvert, 1966, and references therein), relating the alternation between lighter and darker olive-green laminae to seasonally varying diatom flux to the sea floor. High sedimentation rates associated with laminated marine sediments (millimeters to centimeters per year), together with immature coring technologies, meant that the recovery of full Quaternary sequences, or even complete Holocene records, was not possible until the inception of the Deep Sea Drilling Project (DSDP), and the introduction of the Hydraulic Piston Corer (HPC). The HPC was first deployed during DSDP Leg 64 in 1978, in the Gulf of California, recovering 152 m (~250 ka) of marine laminated diatom ooze, interbedded with homogeneous diatom ooze, of late Pleistocene to Holocene age (Schrader et al., 1980; see Figure 2(a)). DSDP Site 480 represented the first complete Quaternary marine laminated sediment sequence recovered. The development of the HPC into the Advanced Piston Corer (APC) during the Ocean Drilling Program (ODP) and Integrated ODP (IODP) led to the recovery of long cores of laminated diatom ooze, including an almost 200 m long, ~160 ka sequence from Santa Barbara Basin, California margin (Behl and Kennett, 1996), a 118 m long sequence from Saanich Inlet, British Columbia, with approximately 60 m of

Holocene laminated diatom-rich sediments (Blais-Stevens et al., 2001) and, most recently, a ~200 m long Holocene sequence from the Adélie Basin, East Antarctic margin (Expedition 318 Scientists, 2010; Figure 1).

Advances in analytical techniques during the 1990s have realized the potential of laminated, diatom-rich marine sediments to provide seasonal-scale proxy ocean and climate records. Almost surgical precision in sampling has been introduced, including small, discrete samples for quantitative diatom abundance work (Barron et al., 2005; Leventer et al., 2002; Sancetta, 1995), and scanning electron microscope (SEM) analysis of intact sequences of laminations on the micron scale to investigate diatom species successions through the seasons and relationships between succeeding laminae (Kemp, 1990). The introduction of SEM-scale analysis to the study of laminated, diatom-rich sediments has unlocked Quaternary proxy paleo-ocean and -climate records that can now be compared with modern instrumental data retrieved from sediment traps and satellite remote sensing of the sea surface (Thunell et al., 1993). The seasonal variations in diatom flux and terrigenous input into the laminated sediments can often be extrapolated to the interpretation of longer time-scale variations through a sequence (Anderson, 1986), and hence laminations can provide analysis of variations from seasonal through to millennial timescales (Kemp, 2003).

Sites of Accumulation of Quaternary Laminated Diatom Ooze

There are two requirements for the formation of laminated diatom ooze in marine sediments: (1) a temporally varying flux of either diatoms or terrigenous grains, or both; and (2) a mechanism for preserving the primary sediment fabric. In the Gulf of California (Figure 1), a classic site of laminated diatom-rich sediment deposition, early workers proposed that either diatom flux varied through the year with terrigenous flux remaining constant, or terrigenous flux varied with biogenic flux remaining constant. The introduction of sediment traps to the study of lakes (e.g., Anderson, 1977), and then to the study of oceans (e.g., Honjo, 1982), made it possible to relate compositionally different fluxes with their seasons of production. This technological advance made it possible to address debates over which flux varied and which remained constant through the year and, in the case of the Gulf of California, it was discovered that both biogenic and terrigenous fluxes varied, with diatoms having two peak flux events per year in the spring and autumn/early winter (Thunell et al., 1993) related to the 'spring bloom' and 'fall dump' of diatoms, respectively (Kemp et al., 2000). The application of SEM-scale analytical techniques to Gulf of California sediments further revealed that the fossil diatom assemblage record reflected the seasonal variations in flux through the water column, with up

Figure 1 Schematic world map showing the location of sites of accumulation of Quaternary diatom-rich laminated sediments discussed in this article.

to five discrete diatom productivity events identified in sediments per year (Pike and Kemp, 1997).

Typical sites of accumulation of laminated diatom-rich sediments occur beneath areas of coastal upwelling. Seasonal variations in the strength or direction of alongshore winds influences the influx of nutrients into the euphotic zone from deeper water, hence the temporal abundance and species composition of the diatoms living in the surface waters. Such sites range from continental shelf silled basins (Figure 3(a)), such as Santa Barbara Basin (e.g., Schimmelmann and Lange, 1996), to open continental slope sites such as along the California and Peru margins (e.g., Anderson et al., 1987; Brodie and Kemp, 1994), to semienclosed seas such as the Gulf of California (Pike and Kemp, 1997). Mechanisms for the preservation of laminated sediments that accumulate in shelfal environments are related to levels of dissolved oxygen at the sea floor. Restricted water circulation in silled basins, such as Santa Barbara Basin (Figure 1), together with high surface water rain of organic material leads to the rapid consumption of dissolved oxygen below sill depth (concentrations below 0.2 ml l^{-1}), the restriction of an active macrofauna, and the preservation of the seasonally varying flux as primary laminations (e.g., Schimmelmann and Lange, 1996, and references therein). Along the continental slope, laminated sediments are preserved where the slope intersects the midwater depth oxygen minimum zone (OMZ; see Figure 3(b)). The oceanic OMZ is strengthened in regions of coastal upwelling due to bacterial degradation of the high flux of organic debris from the nutrient-rich surface waters. Where this OMZ intersects the continental slope, the macrofauna is restricted and variations in flux are preserved in the sediments (e.g., Anderson et al.,

1987). In semienclosed seas, the intersection of the basin slopes with the OMZ also will lead to the preservation of diatom-rich laminations.

During the Quaternary, laminated diatom-rich sediments have also been preserved in the deep-sea beneath areas of open ocean distant from the coasts. Typically, in the deep sea, levels of benthic dissolved oxygen are high enough to support an active, bioturbating benthic faunal community. When laminated diatom ooze is preserved, a mechanism other than prohibitively low levels of dissolved oxygen is required for the preservation of laminations. In the Quaternary, laminated diatom oozes have been described from the North Atlantic and Southern Ocean (Bodén and Backman, 1996; Grigorov et al., 2002). Both of these regions are associated with convergent oceanic frontal systems, which concentrate tangled mats of pennate diatoms and lead to a mass flux of preformed diatom mat laminations to the sea floor (Figure 3(c)), overwhelming the benthic community and preventing bioturbation (Kemp and Baldauf, 1993). In this case, a physical mechanism of diatom-rich lamina preservation is invoked as opposed to the chemical mechanism involved with the occurrence of low benthic dissolved oxygen concentrations.

Diatom fossil records from Quaternary laminated marine sediments can provide us with a wealth of the highest resolution proxy environmental data. This article describes the nature of these records over (i) seasonal and interannual timescales, relating to variations in species composition and abundance through the year, and (ii) orbital timescales, relating to variations in abundance and the presence or absence of the diatom-rich laminations as controlled by large-scale oceanographic and climatic processes.

Intra- to Interannual Diatom Productivity Events from Quaternary Laminated Sediments: Marine Varves

Enclosed and Semienclosed Seas

Diatoms that are highly sensitive to changes in environmental conditions, and laminated marine sediments that contain a well-preserved record of seasonal sediment flux, are a very powerful combination for reconstructing past environments. Investigation of Holocene laminated diatom ooze from enclosed and semienclosed seas, such as the Gulf of California and laminated Pleistocene sapropels from the Mediterranean Sea (Figure 1), highlighted the process of the fall dump (Kemp et al., 2000) as a major mechanism of diatom flux, silica and carbon export to the sediments. In the Gulf of California, sediment trap (Thunell et al., 1993) and fossil diatom assemblage analysis (Pike and Kemp, 1997) showed that there were two silica flux maxima per year (Figure 4(a)). In spring, coastal upwelling associated with strong NW winds promotes high primary productivity along the eastern coast of the gulf that results in a layer of *Hyalochaete Chaetoceros* spp. resting spores (CRS) in the sediments of the deep basins, for example, Guaymas Basin, where the basin slopes intersect the OMZ. In the fossil record of coastal oceans, CRS are typically associated with strong spring coastal upwelling. However, sediment traps in Guaymas Basin showed that the silica flux maxima for the year occurred in late autumn/early winter (Thunell et al., 1993), and the diatom fossil record associated with this event, as recorded by SEM-scale sediment fabric analysis, consisted of large centric diatoms such as *Coscinodiscus asteromphalus*, *Coscinodiscus oculus-iridis*, *Coscinodiscus granii*, *Rhizosolenia bergonii*, and *Stephanopyxis palmeriana*. Pike and Kemp (1997)

concluded that these diatoms had been growing slowly at depth during the summer when there was a well-stratified water column and low intensity southerly winds. When the autumn/early winter storms mixed the water column as the winds shifted to become more northerly, these diatoms were deposited en masse, creating the opal flux maxima record in the sediment traps. A similar interpretation was reached for well-preserved Pleistocene sapropels (organic carbon-rich deposits) from the Mediterranean (Kemp et al., 1999). Here, diatoms such as *Rhizosolenia* spp. and *Hemiaulus hauckii*, which form long chains that tangle together to form ‘mats,’ grow during the summer season of strong water column stratification. These diatoms take advantage of nutrients trapped at depth in the stratified water column and then, by regulating their buoyancy, move up to the surface to photosynthesize (Kemp et al., 2000). Hence, the study of these low-latitude diatom fossil records from the Gulf of California and the Mediterranean raised awareness that high diatom export production need not be closely coupled to coastal or oceanic upwelling, as has been the classic interpretation, but could

also be the result of deposition following the breakdown of summer water column stratification and a fall dump of a diatom population that had been growing slowly over the summer in a deep chlorophyll maximum (DCM; Kemp et al., 2000).

In the Pleistocene Mediterranean Sea (Figure 1), the primary method of promulgating opal and organic carbon flux to the sediments, to form sapropels, was through the mat-forming diatoms *Rhizosolenia* spp. and *H. hauckii*. Although this was not the case for the Holocene Gulf of California laminated diatom-rich sediments, a typical mat-forming diatom was recorded here – *Thalassiothrix longissima*. Analysis of the stratigraphic position of *Thalassiothrix longissima* diatom mats within the Holocene varve led to the interpretation that *Thalassiothrix longissima* was transported into the gulf with subtropical surface waters during summer, but was deposited in the autumn along with the fall dump flora as wind speeds increased and wind direction changed to become more northerly (Pike and Kemp, 1997). Today, subtropical Pacific surface waters are advected far into the Gulf of California during El

Niño years, as the warm El Niño water mass flows northwards along the western edge of continental North America. Frequency analysis of the abundance of *Thalassiothrix longissima* diatom mats within an early Holocene section of laminations revealed three dominant frequencies: ~11 years, ~22–24 years, and ~50 years (Pike and Kemp, 1997). These frequencies are related to cycles in solar activity and, hence, the diatom record would suggest that in the early Holocene in the eastern Pacific Ocean, the frequency of El Niño, hence the import of *Thalassiothrix longissima* diatom mats into the gulf, was in part regulated by solar activity (Pike and Kemp, 1997).

Continental Shelf Basins

There is an extensive Quaternary laminated sediment fossil diatom record from silled continental shelf basins from both low and high latitudes. A well-known site for the accumulation of varved sediments is the Santa Barbara Basin on the California margin (Figure 1), a silled basin situated beneath a region of strong coastal upwelling that supports seasonally high primary production of diatoms. The Holocene record has been well documented (Schimmelmann and Lange, 1996 and references therein); however, the recovery of a long drill core, ODP Site 893, extended the record back into the late Pleistocene, over 160 ka (e.g., Bull et al., 2000). Laminations are preserved during warm interglacials or interstadials when bottom water ventilation of the basin is weak and bottom water dissolved oxygen concentrations are low (Behl and Kennett, 1996). The laminations form varves, which are either couplets of silt-rich and silt-poor laminae, or triplets of silt-rich, silt-poor, and diatom ooze laminae (Bull and Kemp, 1995). Lithogenic material is delivered primarily as terrestrial run-off during the winter rainy season whereas diatom flux occurs mainly during the spring and summer, related to the intensity of coastal upwelling over the basin. The diatom ooze laminae range in thickness from <20 µm to 2 mm, with a mean thickness of 0.25–0.75 mm, and are composed of vegetative remains and resting spores of *Hyalochaete Chaetoceros* spp., predominantly *Chaetoceros radicans*. Some thicker laminations show a succession of decreasing vegetative remains and increasing resting spores upward, with the very thickest laminae containing sublaminae of other genera (Bull and Kemp, 1995). The range in thickness of the diatom ooze laminae reflects increased or decreased diatom productivity, hence, efficiency of coastal upwelling, whereas the thickness of the terrigenous components is linked to the amount of rainfall and subsequent run-off from the continent. This decoupling of formation processes between diatom and terrigenous laminae means that in Santa Barbara Basin, the varves can be used to assess the concurrence of changes in marine productivity and terrestrial run-off in relation to oceanographic/climatic events such as El Niño (Bull et al., 2000). Bull et al. (2000) investigated the cyclicity and phase relationships between different laminae types from an interval of triplet laminations dated at 160.2 ka (marine isotope stage, MIS, 6.2). They showed that 3.1, 8.4, and 8.8 year cycles in terrigenous lamina thickness and total varve thickness could be related to similar frequencies in modern El Niño time series. During modern El Niño, there is increased rainfall over the California coast and, hence, increased terrestrial run-off onto the shelf. Cycles of 3.5, 7.3, and

7.6 years in the diatom laminations could also be related to El Niño and reflect reduced marine productivity associated with warmer waters expanding northward along the North American coast and reducing the effectiveness of upwelling to reach cold, nutrient-rich deeper waters (Bull et al., 2000). Further, the changes in thickness of the terrigenous laminae and diatom ooze laminae are antiphased which is expected because the impact of El Niño is to simultaneously increase run-off from land and decrease marine productivity.

In recent years a number of late Quaternary laminated diatom ooze deposits have been recovered from continental basin and trough sites around Antarctica (Barker et al., 1999; Expedition 318 Scientists, 2010; Leventer et al., 2006). These basins and troughs were sites of exceptionally high sedimentation, particularly during the rapid warming following the last glacial period. For example, Palmer Deep (Figure 1), a funnel-shaped depression on the western Antarctic Peninsula shelf which acts as a large natural sediment trap, had an average radiocarbon-derived linear sedimentation rate of $0.25 \text{ cm year}^{-1}$ during the last deglaciation (Domack et al., 2001; as recalibrated in Maddison et al., 2005). Despite this low sedimentation rate, individual varves can be in excess of 5 cm thick in the early deglaciation (Maddison et al., 2005). Iceberg Alley, a linear-shaped trough on the MacRobertson Shelf, East Antarctic margin (Figure 1), had a radiocarbon-derived linear sedimentation rate of 0.5 cm year^{-1} during a similar postglacial interval (Stickley et al., 2005), but with individual varves being over 8 cm in thickness (Figure 2(b)). Compared with average coastal high sedimentation rates measured in cm per thousand years, sedimentation rates of cm per year represent much higher biological productivity in the surface waters, and hence higher flux of diatoms to the sediments. Analysis of the seasonal sequence of diatom assemblages recorded in these sediments reveals evidence of dynamic changes around the coast of Antarctica during deglaciation. In the Palmer Deep postglacial laminated diatom ooze, thick laminations composed of CRS (see Figure 5(a) and 5(b)) are deposited following the spring bloom of vegetative *Hyalochaete Chaetoceros* spp. In Antarctic coastal waters, as opposed to coastal upwelling at low latitudes, *Chaetoceros* spp. (Hyalochaete) are typical indicators of spring waters at the sea ice edge. As the sea ice melts, a freshwater cap traps nutrients in the surface waters leading to a bloom of *Chaetoceros* spp. (Hyalochaete) diatoms. When the sea ice has completely melted and the nutrients in the water are depleted, CRS are deposited to form a thick lamination in the sediments (Maddison et al., 2005). In the summer, as the water column becomes increasingly oligotrophic, a more typical mixed Antarctic coastal assemblage takes over, comprising diatoms such as *Corethron pennatum*, *Coscinodiscus bouvet*, *Odontella weissflogii*, *Fragilariopsis* spp., and *Thalassiosira antarctica*. During the immediate postglacial times, the summer laminations are often characterized by a succession of sublaminae dominated by different species, related to pulses of upwelled circumpolar deep water replenishing nutrients on the shelf, or to advected water masses (Figure 4(c)). CRS sublaminae occur in earliest summer when the influx of new nutrients restimulates the waning spring *Chaetoceros* (Hyalochaete) population. *Corethron pennatum* sublaminae occur early in summer, perhaps deposited from a water column that is still partially stratified but with no sea ice

Figure 5 Scanning electron microscope secondary electron images of examples of Quaternary diatom laminations. (a) Low magnification image of an *Chaetoceros* (Hyalochaete) resting spore lamina-parallel sediment surface (ODP Hole 1098A, 44.1341–44.1261 mcd; scale bar = 100 μm). (b) High magnification image of a *Chaetoceros* (Hyalochaete) resting spore lamina (scale bar = 10 μm). (c) Low magnification image of a *Thalassiosira antarctica* resting spore lamina-parallel sediment surface (ODP Hole 1098A, 44.3965–44.3735 mcd; scale bar = 100 μm). (d) *Thalassiosira antarctica* resting spore (scale bar = 10 μm). (e) Low magnification image of a pennate diatom mat demonstrating the inherent strength of the mat that enables it to be sculpted (NBP0101 KC09, 255 cm; scale bar = 1 mm). (f) Higher magnification image of a pennate diatom mat showing the long thin frustules of *Thalassiothrix antarctica* that inhibit bioturbation (NBP0101 KC09, 255 cm; scale bar = 100 μm).

remaining. Sublaminae of *Coscinodiscus bouvet* are most likely deposited from advected water masses from further north along the peninsula, associated with summer storms. Near the top of the summer laminations, *Thalassiosira antarctica* sublaminae often occur as the last bloom of the year before light levels drop and sea ice reforms over the region (Maddison et al., 2005). It seems from this, and other laminated records recovered from around the Antarctic margin, that *Thalassiosira antarctica* is a good indicator in the sediment record for autumn diatom flux (Pike et al., 2009).

In Iceberg Alley, MacRobertson Shelf, the postglacial diatom record is similar to that of Palmer Deep; however, here the seasonal succession of diatoms is expressed within the thick 'spring' laminae, as opposed to the summer laminae in Palmer Deep (Figure 4(d)). The spring laminae are dominated by CRS as in Palmer Deep; however, near the top of the CRS laminae, the concentration of diatoms such as *Corethron pennatum* and *Rhizosolenia* spp. increases (Stickley et al., 2005). The early postglacial environment was characterized by *Corethron pennatum*, whereas the later postglacial was characterized by increased abundance of *Rhizosolenia* spp. reflecting the gradual move to

relative oligotrophy and less persistent sea ice when compared with the early postglacial. This increase in *Corethron pennatum* and *Rhizosolenia* spp. toward the top of the spring lamination suggests that as the *Chaetoceros* spp. (Hyalochaete) exhaust the nutrients in the surface waters the other, more oligotrophic, diatoms gradually take over until summer (i.e., the second lamination of the couplet), when the water column stratification eventually breaks down and the typical Antarctic mixed flora of diatoms takes over (Stickley et al., 2005). During the postglacial in Iceberg Alley, it is suggested that a calving bay reentrant existed (a fjord-like indentation in the ice-sheet edge that forms a open water bay surrounded by cliff of ice and, into which, icebergs calve), surrounding the trough and trapping nutrients and flux within the trough (Leventer et al., 2006), thus the extremely high sedimentation rates and diatom flux can be attributed to both high biological productivity resulting from high nutrients in the water column, and sediment focusing within the trough. The investigation of these laminated sediments from Iceberg Alley, together with others (laminated and nonlaminated) from the East Antarctic margin (Adélie Basin, Mertz Ninnis Trough and Svenner Channel) have led to the description of a new proxy for annual sea ice persistence and winter sea concentration (Pike et al., 2009). When the ratio of abundance of *Porosira glacialis* resting spores:*Thalassiosira antarctica* resting spores is less than 0.1, winters and springs are relatively warm, with annual sea ice duration of ~7.5 months per year and winter sea ice concentration of ~70%. When this ratio is greater than 0.1, winters and springs are relatively cool, with much greater than 7.5 months of annual sea ice cover and winter sea ice concentrations of ~80%. This relative abundance threshold between the two diatoms increases at the transition between the relatively warm Antarctic hypsithermal and the cool Neoglacial (transition at approximately 4000 cal year BP along the East Antarctic margin), indicating the sensitivity of this diatom proxy to recent climate change (Pike et al., 2009).

High-Latitude Fjords

Thickly laminated diatom-rich sediments also sometimes accumulate in fjords, for example, Effingham Inlet and Saanich Inlet (Figure 1), British Columbia, Canada (Blais-Stevens et al., 2001; Chang and Patterson, 2005). Saanich Inlet is a silled fjord with freshwater input at its head which results in weak flushing of the surface waters and isolation of the waters below sill depth. High surface water productivity leads to severely reduced benthic dissolved oxygen levels and the preservation of sedimentary laminations. ODP drilling in Saanich Inlet recovered ~60 m of Holocene diatom-rich laminated sediments. Centimeter-scale varves consist of couplets of diatom ooze or diatom mud deposited in spring and summer, with silty clay deposited in winter (Dean et al., 2001). Saanich Inlet varves may have up to 19 sublaminae composed of various diatom species, or assemblages. Following from the winter terrigenous lamina, up to two early spring sublaminae characterized by *Thalassiosira pacifica* or *Chaetoceros* spp. (Hyalochaete) may be deposited as light levels increase and water column stratification begins to be established. In spring, with a strong pycnocline (a zone of rapid increase in density within a layer of the ocean) and high nutrient levels in the surface waters, *Chaetoceros* spp. (Hyalochaete) bloom and a sublamina

is deposited, followed by a sublamina characterized by *Skeletonema costatum*. The summer portion of the varve is characterized by one to many sublaminae of *Chaetoceros* spp. (Hyalochaete). The number of summer sublaminae, or blooms in the water column, is related to a tidally controlled input of new nutrients and diatom seedstock into the fjord. As the water column stability is broken down in autumn, there may be a final bloom and subsequent sublamina of *Chaetoceros* spp. (Hyalochaete) deposited (Dean et al., 2001). Interannual variability in the varved sequence is revealed by presence or absence of *Thalassiosira pacifica* and/or *S. costatum* sublaminae. *Thalassiosira pacifica* is abundant when there is a greater input of freshwater into the fjord during El Niño events, whereas *S. costatum* tends to be more abundant during the cooler periods between El Niño events and negative phases of the Pacific–North American index (Dean et al., 2001).

Centennial- to Orbital-Scale Diatom Records from Quaternary Laminated Sediments

Quaternary laminated sediment sections not only record information about year-on-year variations in diatom assemblages which can be used to reconstruct the annual cycle of hydrographic conditions (Pike and Kemp, 1997), they also record variations over interannual through to millennial timescales (Leventer et al., 2010). In the Gulf of California, investigations of diatom species variations revealed long-term variations in the hydrography and climate of the gulf over the last 15 ka (Barron et al., 2005, and references therein). For example, *Azpeita nodulifera*, a tropical species, was abundant in the Guaymas Basin, central Gulf of California (Figure 1), during the Bølling/Allerød interstadial (14.6–12.9 ka) indicating that the seasonal incursion of warm, tropical waters from the Pacific to the south was strong. *A. nodulifera* was still common during the Younger Dryas stadial (12.9–11.6 ka), but it is associated with an overall reduction in diatom abundance suggestive of tropical, oligotrophic conditions extending throughout the year (i.e., seasonality was reduced; there were no laminations preserved during the Younger Dryas). Between ~11.0 and 6.2 ka, diatom abundance increased, but *A. nodulifera* almost disappears from the records. This indicates intensification in the strength or duration of northwesterly winter winds driving high productivity associated with coastal upwelling and effectively excluding Pacific-derived tropical forms from entering the gulf. The return of *A. nodulifera* to the record during the time period 6.2–5.4 ka indicates the return of southerly sourced tropical water into the gulf and the onset of modern monsoonal conditions with seasonally reversing winds resulting in coastal upwelling in the spring and incursions of warm, tropical waters in the summer. Hence, the diatoms preserved in the Gulf of California laminated sediments can be used to look at long-term, large-scale changes in hydrography and climate of the region.

Along the Peru margin diatom records from laminated sediments have been used to investigate the occurrence of ocean-climate events such as El Niño during earlier Quaternary climates (Brodie and Kemp, 1994). Laminated diatom-rich sediments have accumulated intermittently at ODP Site 686, West Pisco Basin (Figure 1), which is a continental shelf basin

and part of the rapidly subsiding forearc basin associated with the Peru–Chile Trench. Well-developed triplet laminations (Figure 4(b)) comprising an alternation of silt-rich and silt-poor terrigenous laminae with occasional near-monospecific *S. costatum* or, less often, *Hyalochaete* CRS diatom ooze laminations, accumulated during the last interglacial, MIS 5e (Brodie and Kemp, 1994). The triplet laminations represent marine varves whereby the silt-rich and silt-poor terrigenous laminae represent annual variations in continental run-off, and the intermittent diatom ooze laminations are interpreted as mega-blooms associated with anti-El Niño conditions, such as La Niña, when upwelling intensity increased along the Peru margin. Landward of the West Pisco Basin today, however, there is very little annual rainfall and run-off is intermittent, whereas to the north it is believed that only El Niño is capable of producing any significant surface run-off (Brodie and Kemp, 1994 and references therein). The evidence from the diatom-rich triplet laminations and other data such as from alkenone sea-surface temperature reconstructions (Brodie and Kemp, 1994 and references therein) lead to the conclusion that surface waters along the Peru margin were generally warmer during the last interglacial, which would have promoted a more regular rainfall pattern over the continent with more consistent annual run-off – hence the preservation of silt-rich and silt-poor laminations. As stated above, the intermittent *S. costatum* diatom ooze laminae represent deposition from extremely large productivity events likely to be associated with strong La Niña years (Brodie and Kemp, 1994).

Presence or Absence of Diatom-Rich Laminations: Oceanographic Frontal Zones

Accumulations of Quaternary diatom-rich laminations in the deep sea that cannot simply be ascribed a seasonal origin, are associated with the position of major convergent oceanic frontal systems (Figure 3(c)). The taxa associated with these laminated oozes are mat-forming diatoms from the genus *Thalassiothrix* (e.g., Bodén and Backman, 1996; Grigorov et al., 2002). The physical oceanographic mechanism responsible for the production of accumulations of laminated, diatom mat-rich sediments was first described for the Neogene sediments of the eastern equatorial Pacific (Kemp and Baldauf, 1993); however, Quaternary occurrences of diatom mat deposits have since been described and ascribed a similar mechanism. In the North Atlantic at Site EW9303-17 on the west flank of the Reykjanes Ridge (Figure 1), a 3-m-thick interval of laminated diatom ooze was described as being composed of monospecific *Thalassiothrix longissima* diatom mats (Bodén and Backman, 1996). Preservation of these diatom mats at the sea floor is not due to low sea-floor dissolved oxygen levels as the deep Atlantic is well oxygenated, but rather to the physical suppression of the benthic faunal burrowers by the impenetrable, mesh-like nature of the diatom mats themselves. (Figure 5(e) and 5(f) show examples from the Antarctic that demonstrate the strength of these pennate diatom mats.) This interval accumulated during MIS 5e, that is, the last interglacial. The accumulation of these diatom mats at this site, at this time, is related to the position of the subarctic convergence where the warm, salty North Atlantic and Irminger Currents meet cold, less saline Labrador Sea water. *Thalassiothrix*

longissima mats (colonies) carried in the colder water get subducted at the frontal zone to then ‘pop-up’ to the surface on the warmer more oligotrophic side of the front in order to photosynthesize. Here, they exhaust the already low nutrients, the diatoms die and sink to the sea floor to accumulate in a narrow band beneath the front. Oceanic frontal systems are often dynamic and migrate with changing climates, so the presence or absence of the laminated *Thalassiothrix longissima* diatom mat deposits can be used to track the frontal systems over time; for example, the subarctic convergence was likely positioned over site EW9303-17 during the last interglacial (Bodén and Backman, 1996) but was elsewhere, perhaps further to the south, during the ensuing glacial period.

In the South Atlantic, Pleistocene laminated diatom mat deposits have accumulated beneath the Polar Front at approximately 50° S, and were recovered from ODP Site 1093 (Figure 1), among others, during ODP Leg 177 (Grigorov et al., 2002). These Southern Ocean laminated diatom mat sediments are composed of *Thalassiothrix antarctica*. Similar to the North Atlantic, the laminated sediments appear to have been deposited during either interglacials (e.g., MIS 11 and 29) or the transitions into interglacials (e.g., MIS12/11 transition). In contrast to the diatom record from the North Atlantic, the laminated diatom ooze of the South Atlantic appears to contain a regular succession of diatom species in couplets, for example, *Thalassiothrix antarctica* diatom mats followed by a mixed centric/pennate diatom lamina in the MIS 12/11 interval. In the older interglacial (MIS 29), *Thalassiothrix antarctica* is followed by either by a mixed centric/pennate diatom lamina or *Fragilariopsis kerguelensis* lamina, and then centric diatom lamina. These successions imply that the laminated diatom mat deposits from the Polar Front region of the Southern Ocean could be recording some seasonal variations as well as the physical position of the Polar Front itself (Grigorov et al., 2002).

Summary

Diatom fossil records from Quaternary laminated marine sediments reveal evidence for climate and ocean variability over subannual, interannual, millennial, and orbital timescales. Seasonal diatom species or assemblage successions can reveal information about the nature of the prevailing water column process producing the silica flux, for example, upwelling or breakdown of water column stratification. Interannual variations in the occurrence of particular species, or in the make up of the whole diatom assemblage can provide a valuable indication of the behavior of phenomena such as the El Niño–Southern Oscillation during past climate states. In locations where long, late Quaternary laminated sediments sequences are recovered, the changes in the diatom ooze lamina assemblage over centennial to millennial timescales can reveal changes in local and region-scale ocean circulation and climate. Laminated diatom ooze also accumulates in the open ocean in association with convergent oceanic frontal systems. Here the laminations are composed of tangled diatom mats and are not necessarily seasonally deposited, however, the presence or absence of the laminated diatom mat deposits can be used to track the movement of the oceanic fronts over glacial–interglacial timescales.

Introduction

Marine planktonic diatoms are single-celled, photosynthetic, siliceous-walled algae. In the oceans, diatoms are restricted to cold, nutrient-rich regions where silicic acid is not limiting, such as in the polar regions, the coastal and equatorial upwelling systems, and in coastal areas. The most important factors that determine the distribution and abundance of diatoms in surface waters are sea-surface temperatures (SSTs), sea-ice conditions, macro- and micronutrient levels, stability of the surface water layer, light levels, and grazing. Surface-water productivity and dissolution in the water column and at the water-sediment interface are major processes dictating the diatom flux to the seafloor and preservation of diatom valves in sediments.

Preservation of diatoms in sediments of the North Atlantic Ocean through geologic time has been highly variable. The North Atlantic Ocean and the Nordic Seas were regions of high biosiliceous productivity until the intensification of Northern Hemisphere glaciations during the late Miocene and Pliocene. Diatoms are one of the most abundant microfossil groups preserved in sediments of Paleogene and early to mid-Neogene age in this region, organic-walled palynomorphs are also abundant, whereas calcareous microfossils are less abundant. In the central Arctic, diatoms were prolific in the late Cretaceous (Davies et al., 2009) and middle Eocene (Stickley et al., 2008, 2009; Suto et al., 2009). Since diatom species have undergone rapid evolution through the Cenozoic, it has been possible to establish a high-resolution biostratigraphy for the area. Based on the Deep Sea Drilling Project (DSDP) Legs 81 and 94, Baldauf (1984, 1987) established a Cenozoic diatom biostratigraphy for the middle- to high-latitude North Atlantic Ocean. Most of the fossil diatom species of the Nordic Seas and central Arctic are, however, endemic to these areas. Therefore, a separate diatom biostratigraphy has been developed for the Nordic Seas, and is underway for the central Arctic based on the DSDP Leg 38 material. Schrader and Fenner (1976) and Dzinoridze et al. (1978) proposed diatom biostratigraphies for the Nordic Seas. Meanwhile, development of drilling techniques and availability of reliable paleomagnetic stratigraphy enabled the development of a new, high-resolution Neogene diatom biostratigraphy for the Nordic Seas based on the Ocean Drilling Program (ODP) Leg 151 material (Koç and Scherer, 1996). The late Paleogene diatom biostratigraphy of Scherer and Koç (1996) from ODP Leg 151 material vastly improved and built on earlier works but calibration of these diatom datums to the geomagnetic polarity time scale (Gradstein et al., 2004) has yet to be achieved. Currently, Paleogene dinoflagellate cyst stratigraphy is better defined than that for diatoms in the Nordic seas (e.g.,

Eldrett et al., 2004); and future integrated stratigraphies are anticipated.

Until 2004, little information existed on central Arctic pre-Quaternary diatoms. What was known was limited to a few short piston cores from the Alpha Ridge such as the USGS cores FL-437 (late Cretaceous) and FL-422 (middle Eocene; Dell'Agnese and Clark, 1994) and the Canadian CESAR 6 core (late Cretaceous; Barron et al., 1985). Recently, Davies et al. (2009) made significant advances in our understanding of pre-Cenozoic Arctic diatom ecosystems by describing late Cretaceous seasonality from diatomaceous laminations within the CESAR 6 core. However, in 2004, Integrated ODP (IODP) Expedition 302, 'The Arctic Coring Expedition' (ACEX) unearthed arguably the most significant find of Paleogene siliceous microfossils in nearly 2 decades. Hundred meters of early middle Eocene, organic-rich, finely laminated sediments were recovered that contain abundant marine, sea ice, and freshwater siliceous microfossils (Onodera et al., 2008; Stickley et al., 2008, 2009; Suto et al., 2009) indicating high production and allowing intriguing insights into central Arctic paleoenvironments during the start of Cenozoic cooling. Largely endemic diatoms including the oldest known sea-ice diatoms (Stickley et al., 2009) other diatoms, ebridians, and silicoflagellates were preserved, along with very high abundances of chrysophyte cysts, the endogenously formed resting stage of freshwater algae. Continuing work on the siliceous microfossils of the ACEX cores, including examination of the laminations (cf. Stickley et al., 2008), is helping us understand the consequences of Cenozoic cooling and the role the Arctic played in important climate feedbacks.

Pleistocene Diatom Record

Biostratigraphy

Pleistocene sediments of the Nordic Seas are mostly barren of diatoms. In contrast to this, sites south of Iceland such as ODP Site 919 from the Irminger Basin and Site 983 from the Gardar Drift are sites with high Pleistocene accumulation rates and well preserved, abundant diatoms (Figure 1). Based on these sites, the resolution of the high-latitude North Atlantic Pleistocene diatom biostratigraphy established by Baldauf (1987) has been refined (Koç and Flower, 1998; Koç et al., 1999, 2001). Eight Pleistocene diatom datum events are identified and, for the first time, tied directly to the oxygen isotope record and paleomagnetic stratigraphy at these sites (Figure 2). These datum events are:

- the last occurrence (LO) of *Proboscia curvirostris* at 0.3 Ma,
- the LO of *Thalassiosira jouseae* at 0.3 Ma,

Figure 1 General surface circulation of the northern North Atlantic Ocean and the location of the cores cited for Pleistocene diatom records. In cores marked with dots, the last occurrence of *Proboscia curvirostris* is correlated to the oxygen isotope stratigraphy of the core. Stars depict sites where *P. curvirostris* has been observed. MD depicts cores taken by the French RV Marion Dufresne during the IMAGES cruises. All other cores are Deep Sea Drilling Project (DSDP) or Ocean Drilling Program (ODP) cores. Surface currents are illustrated with arrows as follows: NAD, North Atlantic Drift; IC, Irminger Current; NC, Norwegian Current; EGC, East Greenland Current; WGC, West Greenland Current; LC, Labrador Current (Koç et al., 2001).

- the LO of *Nitzschia reinholdii* at 0.6 Ma,
- the LO of *Nitzschia fossilis* at 0.68 Ma,
- the LO of *Neodenticula seminae* at 0.84 Ma,
- the first occurrence (FO) of *Neodenticula seminae* at 1.25 Ma,
- the FO of *Proboscia curvirostris* at 1.53 Ma, and
- the FO of *Pseudoeunotia doliolus* at 1.89 Ma.

Most of these datums are isochronous (i.e., occur at the same time) across the middle–high latitudes of the North Atlantic and the North Pacific. Based on these datums four high-latitude North Atlantic diatom zones have been proposed for the Pleistocene: the *Nitzschia reinholdii* zone, the *Neodenticula seminae* zone, the *Proboscia curvirostris* zone, and the *Thalassiosira* (*Shionodiscus*) *oestrupii* zone (Koç et al., 1999).

Paleoceanography

Fluctuating Pleistocene climatic conditions had a major impact on diatom productivity in the high-latitude North Atlantic. Diatom abundance and preservation at Site 919 and 983 covary with the oxygen isotope record of the sites in response to changing oceanographic conditions affecting diatom productivity (Koç and Flower, 1998; Koç et al., 1999; Figure 2). Generally, interglacials relate to high diatom productivity, whereas

sediments representing glacial stages are often barren of diatoms. However, during glacial stages 18, 20, and 30, there was significant diatom production and preservation.

During the late Quaternary glacial periods, Northern Hemisphere oceanic polar fronts and sea-ice migrated southward, with some of the most dramatic changes occurring in the mid- to high-latitude North Atlantic (CLIMAP Project Members, 1981). Reduced surface-water productivity during glacial periods indicates that these were the intervals during which the Polar Front migrated southeastward, thereby covering Sites 919 and 983 with sea ice. Considering the modern proximity of the sea-ice margin to the area, it is highly probable that these diatom-barren glacial intervals reflect periods when these sites were covered by year-round sea ice. On the other hand, the presence of significant diatom production during glacial intervals associated with marine isotope stages (MIS) 18, 20, and 30 indicates open marine conditions at sites south of Iceland during these times. These glacial stages fall within the first 100 ka cycles following the mid-Pleistocene transition, and the benthic oxygen isotope records indicate that these glaciations were not as severe as the late Quaternary glacial periods.

Mid-Pleistocene transition

Neodenticula seminae is part of the modern diatom assemblage of the middle- and high-latitude North Pacific. In the North Atlantic, this species is limited to the time interval of 0.84–1.26 Ma (Koç et al., 1999; Figure 3), but has recently been found in plankton samples from the North Atlantic – possibly a consequence of diminishing sea ice in the modern Arctic facilitating open water exchange between the Pacific and Atlantic (Reid et al., 2007). However, Baldauf (1986) interpreted the occurrence of *Neodenticula seminae* in North Atlantic Quaternary sediments as evidence for the presence of cool, low-salinity surface waters in the central North Atlantic during the early Quaternary. The interval of *Neodenticula seminae* in the North Atlantic straddles the transition from the dominance of 41 ka cycles in the climate records to the dominance of 100 ka cycles. It is, therefore, possible to take the FO of *Neodenticula seminae* in the North Atlantic as an indicator for cooling, which started 1.26 Ma, leading to the establishment of the 100 ka cycles and intensified glaciation. The presence of *Neodenticula seminae* in North Atlantic sediments is, therefore, attributable to the unique conditions related to the mid-Pleistocene transition. Lessons from modern studies (e.g., Reid et al., 2007) should, however, also be considered.

LO of *Proboscia curvirostris*

The youngest diatom event observed in North Atlantic sediments is the LO of *Proboscia curvirostris* (Jousé) Jordan and Priddle (Koç et al., 2001). *Proboscia curvirostris* is a robust species that can easily be identified in fossil assemblages, and therefore is a practical biostratigraphic tool. Its distribution stretches from 40°N to 80°N in the North Atlantic (Figure 1).

The extinction of *Proboscia curvirostris* is latitudinally diachronous through MIS 9–8 within the North Atlantic (Figure 4); a phenomenon closely related to the paleoceanographic development of the area. *Proboscia curvirostris* first disappeared within interglacial MIS 9 (324 ka) from the northern

Figure 2 ODP Site 983 relative diatom abundances (B, barren; R, rare; F, few; C, common; A, abundant) plotted together with the planktonic $\delta^{18}\text{O}$ record against composite depth. Interglacial stages are shaded and numbered. Diatom biostratigraphic events and their ranges are indicated, and correlated to the $\delta^{18}\text{O}$ record (Koc et al., 1999).

areas that are most sensitive to climatic forcing, such as the East Greenland Current (EGC) and the sea-ice margin. It survived in the mid-latitudes North Atlantic until the conditions of the MIS 8 glaciation became too severe (260 ka). In the North Pacific at ODP Site 883, the LO of *Proboscia curvirostris* also falls within MIS 8. This apparent correlation between the North Atlantic and the North Pacific strongly suggests that the extinction of *Proboscia curvirostris* is isochronous between these oceans. The LO of *Proboscia curvirostris* is therefore potentially a highly valuable datum for correlation between the high-latitude North Atlantic and the North Pacific Oceans.

Last glacial period and Heinrich layers

Diatoms are absent in the sediments from the last glacial period in the Nordic Seas. They are also found very infrequently in the sediments of the northern North Atlantic, probably due to extensive sea-ice cover inhibiting diatom production. In contrast, diatom records from the Atlantic upwelling sites reveal maximum productivity during the Last Glacial Maximum (LGM; Abrantes, 2000).

The last glacial period is perturbed by millennial-scale climate variability in the form of Heinrich events (HE) and Dansgaard-Oeschger cycles and there has been a debate on the degree to which massive iceberg discharges associated with HE affected diatom productivity. Sancetta (1992) argued for increased diatom production in the North Atlantic linked

to HE, suggesting that the presence of numerous icebergs would have supported high production through physical (turbulent mixing) and/or biogeochemical (nutrient input) mechanisms. However, a recent detailed study on HE1 and HE4 shows the opposite effect, namely the reduction of diatom production in relation to massive iceberg discharges (Nave et al., 2007). Heinrich layers are deposited mainly between 40°N and 55°N , within the so-called, Ruddiman belt (Ruddiman, 1977). North of the Ruddiman belt during HE4, iceberg discharges had a strong impact on productivity, resulting in a drastic decrease, whereas during HE1, productivity showed a progressive increase through the deglaciation (Nave et al., 2007). Within the Ruddiman belt, massive iceberg discharges had a major effect on productivity during both HE4 and HE1. The possibility that diatom concentrations in ocean sediments had been diluted by ice-rafted detritus was tested by normalization to a constant ^{230}Th flux, and this showed that the enhancement of particle rain rate does not explain the decrease of diatom flux (Nave et al., 2007). The hypothesis that increased nutrient supply from southern source waters would cause an increase in productivity south of the area of maximum iceberg influence was also tested, and no indication for a productivity increase during HE1 and HE4 south of the Ruddiman belt was found. In summary, the massive iceberg discharges associated with HE1 and HE4 had strong impacts on surface ocean productivity, causing its drastic decrease.

Figure 3 Planktonic $\delta^{18}\text{O}$ records of DSDP Site 609 (L. Labeyrie, unpublished data) and ODP Site 983 (Hodell and Kleiven, unpublished data) shown together with their respective paleomagnetic stratigraphies (Koç et al., 1999). In order to compare the timing of events between the middle- and high-latitude North Atlantic, the LO of *Nitzschia reinholdii*, and the last and first occurrence of *Neodenticula seminiae* are plotted at both sites. MIS, marine isotope stage. Inset, scanning electron microscope (SEM) picture of *N. seminiae* (Simonsen and Kanaya) Akiba and Yanagisawa from sample 162-983A-13H-7, 49–50 cm (from plate 1 in Koç et al., 1999).

Figure 4 The LO of *Proboscia curvirostris* plotted on the oxygen isotope stratigraphy of each core (Koç et al., 2001). MIS 9 is shaded, and the substages numbered according to Prell et al. (1986). Sampling intervals are plotted as bars on the left side of the records. Scanning electron microscope (SEM) photograph of *P. curvirostris* Jordan and Priddle and *Nitzschia fossilis* (Frenguelli) Kanaya on the right side, Sample 162-983A-9H-3, 49–50 cm (from plate 2 in Koç et al., 2001).

Diatoms in Surface Sediments

To gain knowledge about present-day diatom ecology and biogeography, the distribution of diatom species and/or assemblages in the surface sediments of the North Atlantic Ocean and the Arctic Ocean have been mapped, and the resulting information has been applied to fossil records to reconstruct past ocean conditions. The high diversity of diatoms in polar and arctic environments makes them one of the foremost tools available for paleoclimatic reconstructions of the sea-ice margin, oceanic fronts, distribution of water masses and quantitative estimates of, for example, past SSTs. Several types of transfer functions, based on different statistical techniques, have been applied to quantify the relationship between the assemblages and the physical parameters. The most common ones are the Imbrie and Kipp technique (Imbrie and Kipp, 1971), the modern analog technique (Hutson, 1980), weighted averaging partial least square (WA-PLS; ter Braak and Juggins, 1993), maximum likelihood, and the artificial neural network approach (Malmgren and Nordlund, 1997).

North Atlantic and the Nordic Seas

Diatoms have proved to be an excellent paleoclimatic tool in the Nordic Seas and the northern North Atlantic. Koç and Schrader (1990) mapped the modern distribution of diatoms in this area based on 87 surface sediment samples and demonstrated that diatoms show good analog relations to modern oceanic conditions and are linearly related to SST. Recently, Andersen et al. (2004a) expanded this calibration set to 139 surface samples and refined the SST equation.

Q-mode factor analysis was applied to this set which defined eight different factors (Figure 5(a)–5(h)). The Arctic Greenland Assemblage (factor 1) with *Thalassiosira angustilineata* and *Thalassiosira trifurcata* mirrors Arctic water masses and has its highest factor loadings in the Greenland Sea. The North Atlantic Assemblage (factor 2) with *Shionodiscus* (*Thalassiosira*) *oestrupii* reflects the influence of the warm North Atlantic Drift. The sub-Arctic Assemblage (factor 3) with *Rhizosolenia hebetata* f. *semispina* and *Rhizosolenia borealis* has its highest loadings in mixed areas between Arctic and Atlantic waters, both northeast and southwest of Iceland. The Norwegian Atlantic Current (NwAC) Assemblage (factor 4) with *Thalassionema nitzschioides*, *Proboscia alata*, and *Thalassiosira angulata* can be used as an indicator of the NwAC. The Sea Ice Assemblage (factor 5) with *Fragilariopsis oceanica*, *Fragilariopsis cylindrus*, and *Thalassiosira hyalina* corresponds to the spring sea-ice limit. The Arctic Assemblage (factor 6) with *Thalassiosira gravida* spores and vegetative cells has its highest loadings in waters between the Polar and the Atlantic waters north of Iceland, and in an intermediate area southwest of Iceland. The East and West Greenland Current Assemblage (factor 7) with *Thalassiosira gravida* vegetative cells has its highest factor loadings under the EGC and the West Greenland Current, continuing into the Labrador Sea. A small plume of this assemblage is also seen in close vicinity to the Arctic front, west of the NwAC. The Mixed Water Masses Assemblage (factor 8) with *Rhizosolenia borealis* has the highest loadings in a conjunction area between the Labrador Sea and the North Atlantic.

Figure 5 The modern geographic distribution and maximum factor loadings ($\times 100$) (shaded for factor loadings 10, 30, and 60) of: (a) the Arctic Greenland Assemblage (factor 1); (b) the North Atlantic Assemblage (factor 2); (c) the sub-Arctic Assemblage (factor 3); (d) the Norwegian Atlantic Current Assemblage (factor 4); (e) the Sea-Ice Assemblage (factor 5); (f) the Arctic Assemblage (factor 6); (g) the East and West Greenland Current Assemblage (factor 7); and (h) the Mixed Water Masses Assemblage (factor 8) (Andersen et al., 2004b).

Because of their close affinity to modern hydrographic regimes, these factors provide us with a tool to reconstruct details of past surface current variability.

Portuguese Margin

The entire Portuguese west coast and western Algarve shelf are areas of upwelling. Diatom assemblages of the Portuguese continental margin have been mapped from 169 surface sediment samples (Abrantes, 1988). The results of the cluster and principal component analyses indicate that diatom species and assemblages are good indicators of the changing character of the upwelling system in this area. For example, small species of the genus *Thalassiosira* occur in areas of persistent upwelling.

Baffin Bay and Davis Strait

The Baffin Bay and Davis Strait area is dominated by a counter-clockwise circulation driven by the cold Baffin Current and the West Greenland Current. Baffin Bay is covered by winter sea ice, and pack ice can last until August in west central Baffin Bay. Analysis of 74 surface sediment samples resulted in the definition of five diatom assemblages in this area (Williams, 1986). These assemblages are closely related to discrete water masses and ice conditions in the area. Baffin Current Assemblage (factor 1) is almost totally dominated by spores of *Thalassiosira gravida*. The Summer Pack Ice Assemblage (factor 2) is dominated by *Actinocyclus curvatulus* with a secondary contribution of *Thalassiosira trifulta*. The West Greenland Current Assemblage (factor 3) is dominated by *Thalassiosira hyalina*. The Fast Ice Assemblage (factor 4) is characterized by *Porosira* sp. Spores, and the Marine Littoral Assemblage (factor 5) is dominated by *Thalassionema nitzschioides* and *Porosira glacialis*.

Laptev and Kara Seas

The modern distribution pattern of diatoms in the Laptev Sea has been mapped from 89 surface sediment samples (Cremer, 1999), and grouped by Q-mode factor analysis into five factors (diatom assemblages): the sea-ice diatom assemblage of the central region of the Laptev Sea, the *Chaetoceros* assemblage of the eastern and southeastern shelf, the *Thalassiosira antarctica* assemblage of the continental slope and deep sea, the freshwater diatom assemblage in the vicinity of river mouths and deltas, and the *Thalassiosira nordenskiöldii* assemblage which shows a patchy occurrence on the central Laptev Sea shelf. The main factor controlling the distribution of diatoms in the Laptev Sea is the input of riverine freshwater during the summer, which strongly affects the salinity conditions and the sea-ice extent.

The distribution of diatom assemblages from the outer Ob and Yenisei estuaries and the adjacent inner Kara Sea shelf have been mapped from 62 surface sediment samples (Polyakova, 2003). A total number of 260 diatom species and varieties were identified in these samples and grouped according to their known salinity tolerances and their phytogeographical distributions. The overall distribution pattern of these groups mainly reflects summer surface salinity and the pattern of sea-ice distribution in the area.

SSTs in the North Atlantic and the Nordic Seas

Diatom-based quantitative SSTs have been developed using Imbrie and Kipp's (1971) 'factor analysis regression' and ter Braak and Juggins's (1993) WA-PLS. Both transfer functions have low root mean square error of prediction ($\sim 1^\circ\text{C}$), a high coefficient of determination r^2 (~ 0.9), and a maximum bias of approximately 1°C (Andersen et al., 2004a; Birks and Koç, 2002).

Transfer functions in the high-latitude North Atlantic have primarily been applied to the deglaciation (Koç and Jansen, 1992) and the Holocene periods (Andersen et al., 2004a,b; Birks and Koç, 2002; Jiang et al., 2005; Koç et al., 1993). Due to extensive sea-ice cover during the glacial periods, it has been impossible to obtain continuous, long diatom records from the high-latitude North Atlantic.

Deglaciation

Diatoms are absent in the LGM sediments of the northern North Atlantic and the Nordic Seas. Diatoms first occurred in the sediments at the start of the deglaciation as the sea-ice cover retreated. Reconstruction of SSTs show that the initial warming of the surface North Atlantic after the LGM happened synchronously between 50°N and 63°N at 13.4^{14}C ka , but was delayed by 1 ka at 72°N (Koç et al., 1996). While a small ice-free corridor opened along the Norwegian coast during the deglaciation, the rest of the Nordic Seas were still covered by sea ice (Figure 6; Koç et al., 1993). The Bølling–Allerød period was a climatically unstable time interval punctuated by several SST coolings (Koç and Jansen, 1992). The magnitudes of these brief coolings were strongly subdued in the North Atlantic compared to the eastern Norwegian Sea. A strong (9°C) gradient (the Arctic front) between the Norwegian Sea and the North Atlantic was present throughout the Bølling–Allerød period. This gradient became even stronger (15°C) during the Younger Dryas period and nearly disappeared during the early Holocene. During the Younger Dryas period, diatom assemblages off the Norwegian coast were dominated by sea-ice species indicating the proximity of the marginal ice zone to the area.

Holocene

The Younger Dryas–early Holocene transition in the Vøring Plateau (the Norwegian Sea), was characterized by a temperature increase of $\sim 3^\circ\text{C}$ within 100 years (Figure 7(a); Berner et al., 2010). The sea-ice species of the Younger Dryas period were very rapidly replaced by warm Atlantic species at the Younger Dryas–Holocene transition. In the Nordic Seas, the early Holocene is dominated by the North Atlantic Assemblage, with its dominant species *Shionodiscus* (*Thalassiosira*) *oestrupii* indicating the invasion of the central and eastern Nordic Seas by the warm Atlantic waters (Figure 8; Andersen et al., 2004a; Koç et al., 1993). After 6.5 cal ka BP, the influence of the North Atlantic Assemblage gradually decreased and Arctic species dominated the assemblage. The diatom-based SSTs indicate a division of the Holocene in the Nordic Seas into three periods: the Holocene climate optimum (HCO)

Figure 6 Reconstructions of paleoceanographic conditions of the Nordic Seas during the deglaciation between 16 and 13 ka (calibrated years) and during the Holocene Climate Optimum at 8 ka together with the dominant Atlantic water species *Thalassiosira oestrupii*. Plotted are the sites of the cores used (dots), polar and Arctic fronts with surface ocean circulation (denoted by arrows) and sea-ice cover (broken pattern). Also plotted are the reconstructions of the areal distribution of the various factors described in Koç and Schrader (1990); factor 1, Norwegian Atlantic Current assemblage (pink); factor 2, Arctic Waters assemblage (green); factor 3, sea-ice assemblage (blue); factor 4, Arctic-Norwegian Waters Mixing assemblage (yellow); factor 5, Atlantic assemblage (red); factor 6, Norwegian-Arctic Waters Mixing assemblage (brown). Areas of overlaps are indicated by the mixture of the two overlapping colors (Koç et al., 1993).

Figure 7 Holocene sea-surface temperature development at (a), the Vøring Plateau, NE Norwegian Sea and (b), the Reykjanes Ridge in the subpolar North Atlantic. The Vøring Plateau record is divided into the HCO, the HTP, and the CLPH (Andersen et al., 2004a; Berner et al., 2008; Berner et al., 2011).

period between 9.5 and 6.5 cal ka BP with SSTs 4 °C warmer than the modern, the Holocene transition period between 6.5 and 3 cal ka BP displaying a gradual SST decrease toward modern values, and the cool late Holocene period between 3 cal ka BP and the present with temperatures around modern SST values (Figure 7(a); Andersen et al., 2004a; Berner et al., 2011). The close similarity of the climate development in the Nordic Seas to high-latitude Northern Hemisphere insolation indicates that it has mainly been driven by insolation forcing (Koç and Jansen, 1994).

The western subarctic gyre is an area of intense mixing of warm and cold waters, which enhances biological productivity. The Holocene sediments of this area are characterized by abundant diatoms. Several levels within the Holocene are dominated by *Rhizosolenia borealis* and *Thalassiothrix longissima*, often as diatom mats (Andersen et al., 2004a,b).

The development of surface ocean climate in the subpolar North Atlantic deviates from the development in the Nordic Seas, both in terms of the timing of the HCO and the stability of SSTs. Over the Reykjanes area, the thermal optimum was not reached until 7–5 cal ka, lagging the insolation maximum by 4 cal ka (Figure 7(b); Andersen et al., 2004b; Berner et al., 2008). SSTs document climatic oscillations with 600–1000-, ~1500-, and 2500-year periodicities, with a time-dependent dominance of different periodicities through the Holocene; a clear change in variability occurred about 5 cal ka BP (Berner et al., 2008). SSTs also provide evidence for Holocene cooling events that, in some cases, correlate to documented southward intrusions of ice into the North Atlantic.

For the last 230 years, August SSTs show a warming trend of ~0.5 °C in the Reykjanes Ridge area (subpolar North Atlantic, Figure 9; Miettinen et al., 2011). The interval from the AD 1770s to the AD 1830s was the coldest period, whereas AD 1860–80 was the warmest period during the last 230 years. The last three decades from the AD 1970s are characterized by a

Figure 8 Changes in Holocene dominance of diatom assemblages (factors 2 and 4) from the Vøring Plateau, NE Norwegian Sea (Andersen et al., 2004a).

Figure 9 Sea-surface temperature record for the last 230 years from the Reykjanes Ridge, the subpolar North Atlantic (Miettinen et al., 2011). Black line shows a linear warming trend, and the great salinity anomalies in the mid-1970s, the 1980s, and the 1990s are shaded.

warming trend showing strong decadal SST variability with several warm years, but also the coldest years since the AD 1820s. These cold years correspond with the documented great salinity anomalies in the North Atlantic, suggesting increased fluxes of cold, low-salinity waters from the Arctic. SST and the August North Atlantic Oscillation (NAO) index (Luterbacher et al., 2002) show similar but reversed multidecadal-scale variability indicating a close coupling between the oceanic and atmospheric patterns. On the multidecadal scale, cold SSTs prevailed during the positive August NAO trends and vice versa. Therefore, the wind-driven variations in volume fluxes of the North Atlantic surface waters could be the major mechanism behind the observed SST trends during the last centuries (Miettinen et al., 2011).

During the Holocene, climate development in the subpolar North Atlantic in the proximity of the Sub-Arctic Front seems to have been mainly affected by (1) incursions of meltwater from the melting remnants of the Laurentide Ice Sheet, (2) increased outflow of polar water from the Canadian Arctic, (3) variations in the production rate of North Atlantic Deep Water (NADW), (4) variations in solar insolation, (5) variations in the strength of the Atlantic Meridional Overturning Circulation, and (6) atmospheric forcing (the NAO) on the multidecadal scale.

Conclusion

Numerous studies have shown that, due to their high diversity in polar and Arctic environments, diatoms are one of the foremost tools available for biostratigraphic and paleoceanographic studies in the mid- to high-latitude North Atlantic. Their high sensitivity to surface ocean conditions have rendered them invaluable especially for reconstructing the sea-ice margin, oceanic frontal migration, distribution of surface water masses and providing quantitative estimates of, for example, past SSTs. They are especially useful for reconstructing subtle SST changes in the interglacials (e.g., the Holocene). Great potential therefore exists in using diatoms for exploring the natural variability of the mid- to high-latitude North Atlantic using quantitative methods to extract information on the magnitudes and frequency of past ocean changes.

Introduction

Throughout much of the middle- to high-latitude North Pacific and equatorial Pacific, diatom fossils occur more frequently in sediments than other microfossils, with a greater diversity of species. Since the 1960s, diatom biostratigraphy and paleoceanography has been well established for the various areas of the Pacific. The diatom records in the Pacific Ocean show correlation with the Earth's orbital parameters and also reveal large and abrupt climatic changes within century to millennial time scales.

Many marine diatom species are endemic to a given region, whereas others have a more cosmopolitan distribution. Modern ecological and biogeographic information needs to be constructed from data on diatom fluxes, species composition of diatom assemblages, hydrographic data sets, and seafloor sediments representing present conditions.

Micropaleontological and paleoceanographic studies on the Quaternary siliceous sediments recovered from the middle to high latitudes of the North Pacific Ocean have been mainly based on diatoms. Studies on the diatoms in these regions have been reviewed by Koizumi (2006). The aim here is to provide an up-to-date account of how diatoms are used in marine environments in the Pacific for the inference of past sea-surface temperatures (SSTs) and for studies of biostratigraphy and phylogenetic evolution.

The modern North Pacific Ocean is subdivided into three different marine environments by the North Pacific Current across the Pacific: the Alaska Gyre containing cold nutrient-rich waters, the Subtropical Gyre containing warm nutrient-depleted waters, and a mixed zone of both subarctic and central water masses between 40° and 42° N (Figure 1). The Kuroshio Current encounters the Oyashio cold water in the mid-western area and forms a western boundary current. The California Current is the related eastern boundary current diverging from the Alaskan Current. The northwest Pacific has three marginal seas: the Japan, Okhotsk, and Bering seas. The Tsushima Warm Current (TWC), a branch of the Kuroshio-bounded western side of the anticyclonic Subtropical Gyre, traverses the Japan Sea. Circulation in the subarctic Pacific is a cyclonic gyre with secondary gyres in the Okhotsk and Bering seas. They are sources for Subarctic Water created by vertical and horizontal mixing. Diatom valves are generally well preserved in sediments under the subarctic Alaska Gyre and the Equatorial Current System. However, diatoms are poorly preserved in sediments under the central portion of the Subtropical Gyre in the North Pacific Ocean.

Paleoceanographic Proxies

Paleoceanographic proxies of diatoms have been constructed by using statistical methods comparing the spatial distribution of diatoms in the surface sediments to the primary production,

SST (°C), salinity, and other physical–chemical parameters in the modern upper-ocean conditions. Calibrated relationships have applied to the diatom assemblages in cores to reconstruct past oceanographic conditions.

Sea-Surface Temperature (°C)

Around the Japanese Islands, Northwest Pacific Ocean

Surface water masses around the Japanese Islands show distinct surface-flow patterns, as documented by their physical properties, especially temperature and salinity. Understanding the current patterns of the Tohoku Area off the northeast part of Honshu Island is critical for understanding the complex hydrographic relations between waters in the subtropical and subarctic North Pacific Ocean.

Very complicated hydrographic conditions occur in the 'Perturbed Area' or the 'Mixed Water Region' between the Kuroshio Front to the North of the Kuroshio Extension and the Oyashio Front at latitudes 35–40° N. Numerous meanders and eddies occur along the northern boundary of the Kuroshio Extension (Figure 2). In the Japan Sea, the fan-shaped Subarctic Front at latitude 38–43° N between Cheongjin and Sado Island off the northwestern coast of Honshu Island separates the southern warm-water mass brought in by the TWC from the northern cold-water mass region brought in by the Liman Current.

Regression analysis was performed to estimate the relationship between the ratio of warm- and cold-water diatoms (Td' ratio) in 123 surface sediments around the Japanese Islands and the mean annual SSTs (°C) (Koizumi, 2008). Td' ratios were calculated as follows: $Td' = [(Xw + XW) / (Xw + XW + Xc + XC)]^{-1} \times 100$, where Xw and XW are the frequency of warm-water species, and Xc and XC are that of cold-water species (Koizumi et al, 2004). Figures 3–5 illustrate indicative holoplanktonic species. The annual SSTs (°C) were calculated from the means of the observed SST (°C) data in summer and winter (Figure 6).

There is a strong relationship between Td' and SST for the Tohoku Area and the Japan Sea (Figure 7). There is no systematic bias in the equations. The inferred SSTs (°C) in the Tohoku Area were generally higher than in the Japan Sea despite lower Td' values because the warm-water species *Fragilariopsis doliolus* (Wallich) Medlin and Sims is abundant only in the TWC in the Japan Sea.

Diatom Assemblages Associated with Oceanic Conditions

The Okhotsk Sea

Today, the Okhotsk Sea is a locus of the North Pacific Intermediate Water and also plays a major role as a source area of glacial North Pacific Deep Water formation. The formation of

the Okhotsk Intermediate Water is linked with seasonal sea-ice cover. Diatoms are by far the most abundant microfossils found in the sediments of the Okhotsk Sea and are promising for interpreting past environments (Koizumi et al., 2003).

Four characteristic diatom assemblages were identified from the spatial distribution of 13 major characteristic diatom species and R-mode principal component analysis in 15 surface sediments (Figure 8; Shiga and Koizumi, 2000). These species reflect environmental factors controlling surface water conditions in the present Okhotsk Sea. The assemblages are (1) A sea-ice assemblage, including *Bacterosira fragilis* Gran, *F. cylindrus* (Grunow) Helmck and Krieger, *F. oceanica* (Cleve) Hasle, and *Thalassiosira gravida* Cleve. This assemblage is present within the floating ice or attached to its under side in the area covered with sea ice, mainly in coastal areas in the western

(10) *Rhizosolenia calcar-avis* (Schultze) Sundstrom, DSDP 580-3-6 (25–26 cm). (11) *Actinocyclus ellipticus* Grunow, DSDP 581-3-4 (90–91 cm). (12) *Rhizosolenia imbricata* Brightwell, MD01-2421 (5–6 cm). (13) *Fragilariopsis oceanica* (Cleve) Hasle, P333 (52 cm). Reproduced from Koizumi I (2008) Diatom-derived SSTs (T_d' ratio) indicate warm seas off Japan during the middle Holocene (8.2–3.3 ka BP). *Marine Micropaleontology* 69: 263–281.

Janisch, *Rhizosolenia hebetata* (Bailey) Gran forma *hiemalis* Gran, and *R. styliformis* Brightwell, occur abundantly in the central area of the Okhotsk Sea.

The Bering Sea

The Bering Sea is a gateway between the Pacific and Arctic oceans (Figure 1). The Bering Strait was closed and most of the Bering continental shelf was exposed during intervals of Pleistocene glaciation due to the growth of continental ice sheets, and consequent lowering of sea level (Sancetta, 1983).

In the Bering Sea, the relative percentages of *Fragilariopsis* spp., including *F. cylindrus* (Grunow) Helmck and Krieger and

F. oceanica (Cleve) Hasle, vary from 0% to 76% in 153 core tops from locations that experience between 0 and 11 months of sea ice, (Caissie et al., 2010; Sancetta, 1981). Relative percentages of *Fragilariopsis* spp. have been related to the presence of sea ice (1) less than 3.5% indicating perennially ice-free conditions, (2) between 13% and 18% indicating that sea ice was present 1–4 months per year, and (3) greater than 19% indicating that sea ice was present more than 4 months per year.

Off the Oregon and California Coasts, Northeast Pacific Ocean

Diatom assemblages in regions of high productivity in transitional climate regimes off the coasts of southern British Columbia to northern California in the northeast Pacific Ocean (Figure 1) preserve paleoceanographic information about the coastal and open-ocean upwelling, and major river inputs.

Comparisons between core tops and sediment traps show that diatom remains reaching the sea floor generally reflect the export of resistant robust diatom species from the upper ocean in the northeast Pacific Ocean (Lopes et al., 2006). The relative abundances of *Chaetoceros* spp. appear to respond to both coastal upwelling and to open-ocean upwelling. In open-ocean settings, *Chaetoceros* spp. track annual average conditions, whereas in the coastal region, *Chaetoceros* spp. are associated with summer/fall production.

Q-mode factor analysis from 30 surface-sediment samples with abundant diatoms defines five diatom assemblages that are associated with oceanic conditions (Figure 9): (1) *Chaetoceros* spores are related with coastal upwelling in the area east of 127°W and curl-driven open-ocean upwelling in the area northwest of 46°N. (2) *Thalassionema nitzschiioides* is associated with the warmer subtropical waters. (3) *R. hebetata* is associated with the Subpolar Front in the open ocean. (4) *N. seminae* is related to the intrusions of subarctic water masses into the upwelling system. (5) Freshwater diatoms are related to the influence of freshwater from the continents.

Holocene Deglaciation

Around the Japanese Islands, Northwest Pacific Ocean

Diatom abundance (expressed as diatom valves/g dry weight of sediment) is mainly dependent on the primary productivity of diatoms in the offshore region. Diatom abundances in the Oyashio Area are twice as high as those in the Kuroshio Area because of mixing of the Oyashio intrusion waters and warm-water eddies (Figures 2 and 10). These abundances decreased during the Younger Dryas (YD) and fluctuated during the middle to late Holocene, with an overall increase from 7 to 3 ka and a decrease from 3 ka to the present.

The littoral–neritic cold-water species *Odontella aurita* increased in abundance along the Frontal Zone in the northern margin of the Perturbed Area in the Tohoku Area. In the Japan Sea, the relative abundances of the East China Sea Coastal Water indicator species *P. sulcata* decreased in the northern part more than in the southern part during the YD and Holocene, and also decreased after ~8–9 ka, following the inflow of the TWC carrying oceanic warm-water species. *F. doliolus* was dominant only in the path of the TWC, with its first occurrence

Figure 6 Maps showing the location sites of the 123 surface-sediment samples (black circles) in relation to modern surface water temperatures (°C) in summer and winter around the Japanese Islands. Figure 7 Graph showing the comparison between Td' ratios and calculated annual sea-surface temperatures (SSTs) which is the mean of the observed SSTs (°C) in summer and winter around the Japanese Islands (Koizumi, 2008). The paleo-SSTs (°C) can be estimated using the equations obtained by the regression analysis. Open squares, Tohoku Area; filled circles, Japan Sea. Reproduced from Koizumi I (2008) Diatom-derived SSTs (Td' ratio) indicate warm seas off Japan during the middle Holocene (8.2–3.3 ka BP). *Marine Micropaleontology* 69: 263–281.

(FO) at 8.5–8.0 ka in the southern part, but at 7.5 ka in the northern part (Figure 10).

The Okhotsk Sea

The diatom records from six cores from the Okhotsk Sea showed that during the Last Glacial Maximum (LGM; 21–18 ka), sea ice covered the southwest part of the sea

throughout the whole year, but the eastern and northern parts were characterized by open-sea conditions. Perennial sea ice extended northward, and sea ice was present throughout the whole year over a great part of the sea except for the eastern part during the interval of 18–17 ka. The sea-ice area extended greatly to the south during the interval of 17–11 ka. During the interval of 11–8 ka, there was no perennial ice cover over the whole area, and the ice-free area appeared as the seasonal ice area began to extend to the western part. After 8 ka, the ice-free waters contracted to the present extent (Koizumi et al., 2003; Shiga and Koizumi, 2000).

The Bering Sea

Diatom records in core 51JPC from the Umnak Plateau in the southeastern Bering Sea showed that during the LGM through the early deglacial period (23–17 ka), sea ice was present for more than 6 months each year, with resting spores of *Thalassiosira antarctica* (Fryxell) Doucet and Hubbard (= *Thalassiosira gravis* Cleve) and *Fragilariopsis* spp. dominating. During deglaciation, perennial sea-ice conditions transitioned to ice-free conditions (17–10 ka) coinciding with a high diversity of *Thalassiosira hyalina*, *Thalassiosira nordenskiöldii*, *Thalassionema nitzschoides*, *O. aurita*, *Chaetoceros* resting spores, *Thalassiosira trifurcata*, and *N. seminae* between 15.1 and 13.7 ka. During the Holocene (10–0 ka), a decrease of resting spores of *Chaetoceros* and an increase of *N. seminae* has occurred since the Holocene hypsithermal at 11.5–9 ka (Caissie et al., 2010).

Climate Changes Based on the Diatom-Inferred SSTs (°C)

Around the Japanese Islands, Northwest Pacific Ocean

The Td' -derived paleo-SSTs (°C) in five cores representing the Kuroshio and TWC (Figure 2) decreased during the YD chronozone due to weakening of both currents (Figure 11). On average SSTs (°C) in the YD were 7–9 °C lower than present-day

Figure 8 Maps showing the spatial distribution of scores for each component of R-mode principal component analysis of the diatom assemblage in the surface sediments of the Okhotsk Sea. Pc 1, sea-ice assemblage; Pc 2, subarctic oceanic assemblage; Pc 3, neritic assemblage; Pc 4, assemblage dominated by *Actinocyclus curvatus* Janisch. Reproduced from Shiga K and Koizumi I (2000) Latest Quaternary oceanographic changes in the Okhotsk Sea based on diatom records. *Marine Micropaleontology* 38: 91–117.

temperatures in the Tohoku Area, and 6–9 °C lower than those in the Japan Sea. The amplitudes of fluctuation of the Td' -derived SSTs (°C) after the YD were within 7–9 °C in the Tohoku Area and within 6–10 °C in the Japan Sea. The early Holocene (11.6–8.2 ka) was a transitional period characterized by a long-term increasing trend of temperatures punctuated by several cooling events, while the middle Holocene (8.2–3.3 ka) coincided with the Holocene hypsithermal period and was 1–2 °C warmer than the earlier and later parts of Holocene. The late Holocene (3.3–0 ka) neoglacal period was marked by a generally decreasing trend of the paleo-SSTs (°C) (Koizumi, 2008), reflecting the decreased solar insolation in the Northern Hemisphere summer (see Figure 12).

The middle Holocene warm period was also recognized in the alkenone records in the Tohoku Area (Isono et al., 2009) and indicates the presence of millennial scale, antiphased SST relationships with coastal northern California as shown by the alkenone SSTs, and the abundances of the warm-water diatom species *F. doliolus* (Figure 13; Barron and Anderson, 2010;

Barron et al., 2003). Such antiphase SST variations between east-to-west margins of the mid-latitude North Pacific Ocean are similar to the behaviors of the long-term orbital-scale El Niño-Southern Oscillation (ENSO; Clement et al., 1999; Yamamoto et al., 2004). The antiphase SST variations also correspond to the patterns seen in the modern Pacific-Decadal Oscillation (PDO), where cooler SSTs in the central north-west Pacific Ocean contrast with warmer SSTs in the eastern North Pacific Ocean and eastern equatorial Pacific Ocean during periods of positive PDO (Barron and Anderson, 2010; Mantua et al., 1997).

The Td' -SSTs (°C) fluctuate with a possible periodicity of century to millennial timescales, indicating a strong and regular flow of the Kuroshio Current in the Tohoku Area and TWC in the Japan of the northwest Pacific Ocean after ~10 ka. Those fluctuations are synchronous with abrupt climate events reported from the different paleoclimatic proxy records in many regions of the Northern Hemisphere (Koizumi and Yamamoto, 2011). Decreases of Td' -SSTs (°C) correspond to

Figure 9 Maps showing the spatial distribution of factor loadings for the five factors of Q-mode factor analysis of the diatom assemblage in the surface sediments of the northeast Pacific Ocean. Factor 1, upwelling (*Chaetoceros* spores); Factor 2, subtropical (*Thalassionema nitzschioides* Grunow); Factor 3, subarctic (*Rhizosolenia hebetata* (Bailey) Gran); Factor 4, transitional (*Neodenticula seminae* (Simonsen and Kanaya) Akiba and Yanagisawa); Factor 5, freshwater (freshwater diatoms). Reproduced from Lopes C, Mix AC, and Abrantes F (2006) Diatoms in northeast Pacific surface sediments as paleoceanographic proxies. *Marine Micropaleontology* 60: 45–65.

Figure 10 Graphs showing the spatial and temporal variations of the diatom abundances (10^7 valves/dry g of sediment) and relative abundances (%) of characteristic diatom species in the Tohoku Area, and the relative abundances (%) of characteristic diatom species in the Japan Sea (Koizumi, 2008). *Odontella aurita* (Lyngbye) Agardh (blue line) is an indicator of the littoral–neritic cold-water, *P. sulcata* (Ehrenberg) Cleve (blue line) is an indicator of East China Sea Coastal Water, and *Fragilariopsis doliolus* (Wallich) Medlin and Sims (red line) is an oceanic warm-water species, especially dominant in the Tsushima Warm Current. Vertical lines indicate the modern values. Modified from Koizumi I (2008) Diatom-derived SSTs (T_d' ratio) indicate warm seas off Japan during the middle Holocene (8.2–3.3 ka BP). *Marine Micropaleontology* 69: 263–281.

Figure 11 Graphs showing the spatial and temporal variations of the T_d' -derived SSTs ($^{\circ}\text{C}$) in the Tohoku Area and the Japan Sea (Koizumi, 2008). Vertical dotted lines indicate the modern values. Modified from Koizumi I (2008) Diatom-derived SSTs (T_d' ratio) indicate warm seas off Japan during the middle Holocene (8.2–3.3 ka BP). *Marine Micropaleontology* 69: 263–281.

cooling and to the triple events of high ^{14}C values in the atmospheric residual ^{14}C records (Stuiver et al., 1991), as well as the Bond events in the North Atlantic Ocean (Bond et al., 2001; Figure 12).

The T_d' -inferred SSTs ($^{\circ}\text{C}$) agreed with alkenone-derived summer SSTs ($^{\circ}\text{C}$) in the same core MD01-2421 from a site off the eastern coast of central Japan (Koizumi, 2008). However, the comparison between the diatom-based T_d' - and the

Figure 12 Graphs showing the comparison of variations of the Td' -derived SSTs ($^{\circ}\text{C}$) in cores MD01-2421 and DGC-6, the residual $\Delta^{14}\text{C}$ (‰) (Stuiver et al., 1991), and July insolation at 37°N (W m^{-2}) (Berger, 1978) with the climatic events during the last 13000 years. Blue lines (cold events) and red lines (warm events) indicate the corresponding changes. BC, before Christ. AD, *Anno Domini*; YD, Younger Dryas; PBO, Preboreal Oscillation; HT, Hypsithermal; RWP, Roman Warm Period; DCP, Dark Age Cold Period; MWP, Medieval Warm Period; LIA, Little Ice Age; T1–T4, Triple events comparing Maunder and Spörer perturbations; TWC, Tsushima Warm Current (Stuiver et al., 1991). Reproduced from Koizumi I and Sakamoto T (2010) Synchronous Td' -derived SSTs ($^{\circ}\text{C}$) off Japan with climatic events in the Northern Hemisphere. *Journal of Geography* 119: 489–509 (in Japanese with English abstract).

alkenone-derived (Isono et al., 2009) SSTs ($^{\circ}\text{C}$) in the north-west Pacific Ocean with SSTs ($^{\circ}\text{C}$) estimations in the northeast Pacific Ocean (Barron et al., 2003, 2010) indicate antiphase SST relationships on a millennial scale in the mid-latitude North Pacific Ocean (Isono et al., 2009; Koizumi, 2008).

The cross-spectral analysis of the Td' -derived annual paleo-SSTs ($^{\circ}\text{C}$) in cores MD01-2421 and residual $\Delta^{14}\text{C}$ (‰) indicate a link with fluctuations in atmospheric ^{14}C values of 2400, 1600, 950, and 400–300-year oscillations (Figure 14; Koizumi and Sakamoto, 2010). According to Debret et al. (2007), 1000- and

2500-year cycles are directly forced by solar activity, whereas the 1600-year cycle corresponds to internal oceanic forcing.

The interval from the YD to the early Holocene in the Tohoku Area and the Japan Sea was punctuated by several cooling events: the YD, the Preboreal Oscillation, the 9.9 ka event and the 9.3 ka event. The hypsithermal mid-Holocene in the Tohoku Area and the Japan Sea was punctuated by a series of significant climatic events which fluctuated at ~ 1.5 ka within $1\text{--}2^{\circ}\text{C}$: the 7.4 ka event corresponded with T1 in the triple events of atmospheric high ^{14}C value (Stuiver et al.,

Figure 13 Graphs showing the comparison of the Td' -derived SSTs ($^{\circ}\text{C}$) and $UK'37$ -derived SSTs ($^{\circ}\text{C}$) (Isono et al., 2009) in the Tohoku Area of northwest Pacific Ocean, and the relative abundance (%) of warm-water diatom species *Fragilariopsis doliolus* (Wallich) Medlin and Sims (Barron and Anderson, 2010) and $UK'37$ -derived SSTs ($^{\circ}\text{C}$) (Barron et al., 2003) off northern California of the northeast Pacific Ocean, and the triple events (T1–T4) of similar nature to Maunder and Spörer type perturbations in the residual $\Delta^{14}\text{C}$ (Stuiver et al., 1991).

1991), the 5.5 ka event with T2 (ibid.). The neoglacal late Holocene period in the Tohoku Area and the Japan Sea consists of a 2.8 ka event, the Roman Warm Period (Yayoi Warm Stage), the Dark Age Cold Period (Kofun Cold Stage), the Medieval Warm Period (MWP), and the Little Ice Age (LIA). The antiphase SST variations occurring during the interval between the MWP and LIA in the northwest (Isono et al., 2009; Koizumi, 2008) and northeast (Barron et al., 2010) Pacific Ocean correspond to the combination of behaviors of the ENSO and PDO (D'Arrigo et al., 2001; Gedalof et al., 2002).

Glacial–Interglacial Cycles

Diatom records in the cores from the northwest Pacific Ocean have shown oscillations between warm and cold Pleistocene intervals and have recorded glacial–interglacial cycles twice over the past 150,000 years. Diatom associations and Td' -SSTs ($^{\circ}\text{C}$) imply that the paleohydrography of the northwest Pacific Ocean has corresponded to the environmental changes on an orbital timescale.

The Tohoku Area off Northeast Japan

Diatom assemblages in the southern margin of the Perturbed Area have been controlled by the Kuroshio–Kuroshio Extension, but in the northern margin the composition of the assemblages has changed in response to the expansion of the warm-water eddies detached from the Kuroshio Extension and

the southward Oyashio Intrusion (Figure 2; Koizumi and Yamamoto, 2010).

Reworked and/or displaced diatoms derived from the seafloor are dominant during the glacial periods due to a lower sea level in the near-shore, northern part of the Perturbed Area. The relative abundances of the littoral–neritic association diatom species are higher in the cores in the Kuroshio Extension than in the cores in the northern margin of the Perturbed Area because the flow of the Kuroshio Current northeast along the near-shore of southwest Honshu transports littoral–neritic diatoms into the southern margin of the Perturbed Area.

On the other hand, the oceanic diatom abundances were generally higher during the interglacial phase than during the glacial phase (Figure 15). The abundances of oceanic diatoms in the northern margin of the Perturbed Area were twice as high as those in the cores in the stream axis of the Kuroshio Extension because of the occurrence of regions of localized abundant diatoms associated with mixing of Oyashio Intrusions and warm-water eddies along the Kuroshio Extension that developed in the northern margin area. The periodicities of 41 ka recognized in the variability of the oceanic diatoms correspond to the obliquity (tilt) period, while those at a 23-ka periodicity correspond to the precession band. Vertical and lateral mixing between cold and warm waters associated with glacioeustatic sea level rise occurring since the last glacial period is likely to have the primary production of oceanic diatoms. Fluctuations of oceanic diatom abundances in core MR97-04-1 from the outer margin of the Tsugaru Warm Current show a reversed saw-tooth pattern composed of lower

Figure 14 Graphs showing the cross spectrum between the Td' -derived SSTs ($^{\circ}\text{C}$) in core MD01-2421 and the residual $\Delta^{14}\text{C}$ (‰) by the Blackman–Tukey method during the last 13000 years (Koizumi and Sakamoto, 2010). (a) Power spectrum of the residual $\Delta^{14}\text{C}$ (‰) (Stuiver et al., 1991). (b) Power spectrum of the Td' -derived SSTs ($^{\circ}\text{C}$) in core MD01-2421. (c) Coherence of cross spectrum. (d) Phase of cross spectrum. Reproduced from Koizumi I and Sakamoto T (2010) Synchronous Td' -derived SSTs ($^{\circ}\text{C}$) off Japan with climatic events in the Northern Hemisphere. *Journal of Geography* 119: 489–509 (in Japanese with English abstract).

abundance in shorter cycles and higher values in longer cycles at 132, 100, 70, and 30 ka (Figure 16(a)). The wavelet analysis of oceanic diatom abundances reveals low frequencies at 96–112, 44–64, and 24 ka periods (Figure 16(b)). The higher frequencies at ~ 2.0 , 2–5.6, and 3.2–9.6 ka periods have been recognized over the last 150 000 years.

High Td' -derived paleo-SSTs ($^{\circ}\text{C}$) in middle MIS 5e (Marine Isotope Event 5.5) and MIS stage 1 of the interglacial phase have been recognized in cores in the Tohoku Area, off northeast Japan (Figure 17). SSTs ($^{\circ}\text{C}$) in MIS 5e of the

last interglacial period were $\sim 5^{\circ}\text{C}$ higher than modern values from near-shore cores, but in the off-shore cores the differences are only up to $\sim 1.5^{\circ}\text{C}$. A remarkable decline of the Td' -derived paleo-SSTs ($^{\circ}\text{C}$) has also been recognized in seven cores also corresponding to the Marine Isotope Event 6.0 at the MIS 6/5 boundary, Event 5.2 in MIS 5b (Martinson et al., 1987), and to the ages of the Heinrich events 1–6 in the northern North Atlantic Ocean (Heinrich, 1988).

Fluctuations in the Td' -derived SSTs ($^{\circ}\text{C}$) over 150 000 years show a reversed saw-tooth pattern with the duration of ~ 30 ka in each saw-tooth in the southern core MD01-2421, but a shape of a saw-tooth at ~ 40 ka periods in the northern core MR97-04-1 (Figure 18(a)). The Td' -SSTs ($^{\circ}\text{C}$) records fluctuate at 118-, 60-, 30-, and 23-ka periods (Koizumi and Yamamoto, 2008, 2010). The lower frequencies in 96–112 and 7.2–12.8 ka periods correspond to Bond cycles (Figure 18(b); Alley, 1998). A periodicity ~ 32 ka corresponds to the periodicity of the long-term variation of the ENSO (Clement et al., 1999). The shorter period of 1.4–2.1 ka corresponds to Heinrich events (Heinrich, 1988), Dansgaard–Oeschger cycles (Alley, 1998), the fluctuations of residual $\Delta^{14}\text{C}$ record with variance on ~ 2 ka (Stuiver et al., 1991), and the ~ 2 ka cycle in the variability of ENSO activity (Moy et al., 2002).

The Japan Sea

Diatom abundances in the southern core MD01-2407 were about two times greater on average than those in the northern core ODP Site 797 over the last 150 000 years (Koizumi and Yamamoto, 2011). Core KT94-15-5, located in the northern area of the Subarctic Boundary, showed almost negligible abundances except during MIS 5e, 2, and 1.

Td' -derived paleo-SSTs ($^{\circ}\text{C}$) in core MD01-2407 were $\sim 2^{\circ}\text{C}$ higher than the mean value 15.6°C during ~ 10 ka long intervals in the last interstadial phase MIS 5e and modern interglacial phase MIS 1, and decreased during the period from the middle part of MIS 5e to the middle part of MIS 2 (Figure 19). Diatom-based SSTs ($^{\circ}\text{C}$) in cores ODP Site 797 and KT94-15-5 indicate fluctuations similar to those recognized during the last and modern interstadial phases in core MD01-2407, but the SSTs ($^{\circ}\text{C}$) in the stadial phase could not be reconstructed as very few marker diatoms were found.

Td' -derived SSTs ($^{\circ}\text{C}$) in core MD01-2407 fluctuated at the 48-ka periods between 160–90 and 45–0 ka due to the orbital-obliquity (tilt) cycles, and at 23 ka periods, orbital precession cycles, during the 140–100 ka interval. The predominant periodicities of 2- and 4-ka periods occurred at intervals of 20 and 40 ka over the past 160 000 years, respectively (Koizumi and Yamamoto, 2011).

Mega-Floods During the LGM in Northeast Pacific Ocean

The freshwater diatom abundances in marine sediments off northern California have been used to infer massive discharges of freshwater from the Columbia River and low sea-surface

Figure 15 Graphs showing the spatial and temporal variations of the oceanic diatom abundances (10^7 g^{-1} of dried sediment) in seven cores in the Tohoku Area, northwest Pacific (Koizumi and Yamamoto, 2010). Diatom abundances increase in the interglacial phase, and in the cores recovered from near-shore off the Sanriku coast. The fluctuations show changes from lower abundance variations at shorter cycles to higher values in longer cycles at about 30 ka periods (see Figure 16(a)). Reproduced from Koizumi I and Yamamoto H (2010) Paleoclimatological evolution of North Pacific surface water off Japan during the past 150,000 years. *Marine Micropaleontology* 74: 108–118.

Figure 16 Graphs showing the wavelet analysis for the values of the band ratio oceanic diatom abundance in core MR97-04-1 (Koizumi and Yamamoto, 2010). (a) Time series. (b) Wavelet power spectrum. Solid black line indicates the 10% confidence level (power significance). The contour levels are chosen for 75%, 50%, 25%, and 5% of the wavelet power. More intense colors indicate higher power. The crosshatched region is the cone of influence, where zero padding has reduced the variance. (c) The global wavelet power spectrum (black line). The dashed line indicates the significance for the global wavelet spectrum, assuming the same significance level and background as in (b). The wavelet software provided by Torrence and Compo (1998) is available at URL: <http://paos.colorado.edu/research/wavelet/>. Reproduced from Koizumi I and Yamamoto H (2010) Paleoclimatological evolution of North Pacific surface water off Japan during the past 150 000 years. *Marine Micropaleontology* 74: 108–118.

Figure 17 Graphs showing the spatial and temporal variations of the Td' -derived SSTs ($^{\circ}\text{C}$) in seven cores in the Tohoku Area, northwest Pacific Ocean (Koizumi and Yamamoto, 2010). The high Td' -derived SSTs ($^{\circ}\text{C}$) in middle MIS 5e (Marine Isotope Event 5.5) and MIS 1 of the interglacial phase are correlated among cores (red dotted lines). The remarkable decline of SSTs ($^{\circ}\text{C}$) recognized in seven cores correspond to the ages of the Heinrich events 1–6 in the northern North Atlantic (Heinrich, 1988) and for the Marine Isotope Event 5.2 in MIS 5b and 6.0 in MIS 6 (blue lines; Martinson et al., 1987). White triangles on the left side of each column indicate the age-control points for age model. Reproduced from Koizumi I and Yamamoto H (2010) Paleocceanographic evolution of North Pacific surface water off Japan during the past 150,000 years. *Marine Micropaleontology* 74: 108–118.

Figure 18 Graphs showing the wavelet analysis for the values of the band ratio Td' -derived SSTs ($^{\circ}\text{C}$) in core MR97-04-1 (Koizumi and Yamamoto, 2010). (a) Time series. The fluctuations indicate the shape of saw-tooth at about 40 ka periods since 150,000 years. (b) Wavelet power spectrum. Solid black line indicates the 10% confidence level (power significance). The contour levels are chosen for 75%, 50%, 25%, and 5% of the wavelet power. More intense colors indicate higher power. The crosshatched region is the cone of influence, where zero padding has reduced the variance. (c) The global wavelet power spectrum (black line). The dashed line indicates the significance for the global wavelet spectrum, assuming the same significance level and background as in (b). Reproduced from Koizumi I and Yamamoto H (2010) Paleocceanographic evolution of North Pacific surface water off Japan during the past 150,000 years. *Marine Micropaleontology* 74: 108–118.

Figure 19 Graphs showing the spatial and temporal variations of the Td' -derived SSTs ($^{\circ}\text{C}$) in three cores over the last 150,000 years in the Japan Sea, northwest Pacific Ocean (Koizumi and Yamamoto, 2011). Td' -derived SSTs ($^{\circ}\text{C}$) in cores ODP Site 797 and KT94-15-5 cannot be reconstructed due to the absence of marker diatom species. The high Td' -derived annual SSTs ($^{\circ}\text{C}$) in middle MIS 5e, base 5c and 1 of the warm-climate phase are correlated between cores (red dotted lines). Broken lines indicate the SSTs ($^{\circ}\text{C}$) in the surface sediment of each core. Black triangles on the left side of each column indicate the age-control points for the age model. Reproduced from Koizumi I and Yamamoto H (2011) Oceanographic variations over the last 150,000 yr in the Japan Sea and synchronous Holocene with the Northern Hemisphere. *Journal of Asian Earth Sciences* 40: 1203–1213.

Figure 20 Graph showing the biostratigraphic Quaternary diatom datums in the low-to-middle latitude and middle-to-high latitude regions in the North Pacific Ocean compared to the magnetostratigraphy of Cande and Kent (1995). $\perp$, first occurrence; $\top$, last occurrence.

salinity anomalies more than 400 km away near 46°N between 31 and 16 ka (Lopes and Mix, 2009).

Sea-surface salinity (in psu) was estimated using the formula, $S = 32.323 - 0.1231 \times \text{FD}$ ($r^2 = 0.8$), where FD is

freshwater diatom-relative abundances to total diatoms in 41 core tops. The freshwater diatoms abundantly occurred at 30.5, 27, 23, 20, and 17.5 ka during most of MIS 2 and constituted more than 40% of assemblages in core MD02-2499 off

northern California. The freshwater diatom assemblages were stratigraphically different; in the events older than 25 ka, benthic freshwater diatoms were mainly *Surirella linearis* W. Smith which occurred with relatively high percentages, consistent with a source dominated by either shallow lakes or running water, whereas in the younger events, planktonic freshwater diatoms dominated, including *Aulacoseira granulata* (Ehrenberg) Simonsen, *A. islandica* (O. Muller) Simonsen, *Cyclotella ocellata* Pantocsek and *C. compta* (Ehrenberg) Kützing, which are common in large lakes. This suggests different freshwater sources and/or flooding mechanisms at different times (Lopes and Mix, 2009).

Biostratigraphy

Datum Levels

Deep-sea drilling in the North Pacific Ocean has recovered complete Quaternary marine sequences by drilling multiple holes at a single site, offering excellent material for the study of diatom biostratigraphy and paleoceanography. Significant progress has been made on Quaternary diatom datum levels (biohorizons) that are directly tied to magnetic reversals. Within the low-to-middle latitudes of the North Pacific Ocean, the FO and last occurrence (LO) of *R. praebergonii* Muknina var. *robusta* Burckle and Trainer are placed at 2.5 and 1.7 Ma, the FO of *F. doliolus* at 2.0 Ma, the LO of *R. praebergonii* Muknina at 1.9 Ma, the FO and LO of *R. matuyamai* Burckle at 1.2 and 1.1 Ma, the LO of *Thalassiosira plicata* Schrader at 0.8 Ma, and the LO of *Nitzschia fossilis* (Frenquelli) Kanaya ex Schrader at 0.5 Ma (Figure 20). Within the middle-to-high latitudes, the FO of *N. seminae* is estimated at 2.7 Ma, the LO of *N. kamtschatica* (Zabelina) Akiba and Yanagisawa at 2.6 Ma, the LO of *Thalassiosira convexa* Mukhina at 2.3 Ma, the LO of *Thalassiosira zabelinae* Jousé at 2.1 Ma, the LO of *N. koizumii* Akiba and Yanagisawa at 1.8 Ma, the LO of *Thalassiosira antiqua* (Grunow) Cleve-Euler at 1.7 Ma, the FO and LO of *Proboscia curvirostris* (Jousé) Jordan and Priddle at 1.6 and 0.3 Ma, the LO of *A. oculatus* Jousé at 1.0 Ma, and the LO of *Thalassiosira jouseae* Akiba at 0.3 Ma (Barron, 2003; Koizumi, 2009). Figure 21 illustrates the diagnostic diatom species.

Phylogenetic Evolution

Two events in the phylogenetic evolution of the *Thalassiosira oestrupii* (Osterfeld) Proshkina-Lavrenko subgroup have been related to warming phases during the intervals of 3.4–3.2 and 2.55–2.2 Ma, indicating the southern shifts of the Subarctic Front in the northwest Pacific Ocean (Figure 22; Shiono and Koizumi, 2000). The five members of the *Thalassiosira oestrupii* subgroup have a central fuloportula (a tubular process of some centric diatoms, usually associated with chitin secretion) with three satellite pores and a trifultate structure (Shiono and Koizumi, 2000).

In this subgroup, *Thalassiosira praeoestrupii* Dumont, Baldauf and Barron is distinguished from other members in that it possesses an underdeveloped trifultate fuloportula

Figure 21 Age diagnostic Quaternary diatom species. (1) *Neodenticula seminae* (Simonsen and Kanaya) Akiba and Yanagisawa, DSDP 580-1-3 (2–3 cm); (2) *Neodenticula koizumii* Akiba and Yanagisawa, DSDP 433A-2-1 (27–29 cm); (3) *Neodenticula kamtschatica* (Zabelina) Akiba and Yanagisawa, DSDP 433A-5-5 (8–10 cm); (4) *Thalassiosira jouseae* Akiba, DSDP 579A-2-2 (13–15 cm); (5) *Rhizosolenia matuyamai* Burckle, DSDP 579A-5-5 (25–27 cm); (6) *Rhizosolenia praebergonii* Muknina, DSDP 579A-12-5 (16–18 cm); (7) *Rhizosolenia praebergonii* Muknina var. *robusta* Burckle and Trainer, DSDP 579A-7-1 (23–25 cm); (8) *Thalassiosira convexa* Mukhina, DSDP 433A-2CC; (9) *Thalassiosira plicata* Schrader, DSDP 433A-3-4 (18–20 cm); (10) *Thalassiosira antiqua* (Grunow) Cleve-Euler, DSDP 579A-8-2 (15–17 cm); (11) *Actinocyclus oculatus* Jousé, DSDP 433A-1-1 (66–68 cm); (12) *Thalassiosira zabelinae* Jousé, DSDP 579A-14-2 (2–4 cm); (13) *Proboscia curvirostris* (Jousé) Jordan and Priddle, DSDP 193-2CC; (14) *Nitzschia fossilis* (Frenquelli) Kanaya ex Schrader, DSDP 580-10-5 (110–112 cm); (15) *Fragilariopsis doliolus* (Wallich) Medlin and Sims, GH76-2, P82 (61 cm).

accompanied with operculate basal structure (Shiono and Koizumi, 2001). *Thalassiosira praeoestrupii* is inferred to be the ancestor species of the subgroup because *Thalassiosira praeoestrupii* occurred at about 4.8 Ma. *Thalassiosira praeoestrupii* forma *juvenis* Shiono and *Thalassiosira trifulta*, which have a complete trifultate fuloportula without the operculate basal structure, evolved from *Thalassiosira praeoestrupii* and differentiated from them during the interval of 3.4–3.2 Ma (Figure 22). *Thalassiosira oestrupii* forma *vetus* Shiono is differentiated from *Thalassiosira trifulta* at 2.55 Ma with a longer distance between the fuloportulae on the margin. *Thalassiosira oestrupii* sensu stricta diverged from *Thalassiosira oestrupii* f. *vetus* at 2.2 Ma.

The Subarctic Front, which is a mixed zone of subarctic and central water masses, occurs at 40–42° N of the North Pacific

Figure 22 Graph showing the phylogenetic evolution of the *Thalassiosira oestrupii* (Osterfeld) Proshkina-Lavrenko subgroup are compared to the shift of the Subarctic Front and fluctuation of the surface water temperature (°C) in the northwest Pacific Ocean (Koizumi, 1986; Shiono and Koizumi, 2001). The significant glaciations in mid-northern latitudes at 2.6 Ma as the base of the Quaternary Period are inserted between the intervals of 3.4–3.2 and 2.55–2.2 Ma corresponding to the warm-climate phase.

Ocean (Figure 1). Temporal and spatial shifts of the Subarctic Front have been reconstructed based on diatom paleoclimatic data at DSDP Sites 579 and 580 in the middle latitude of the northwest Pacific Ocean (Figure 22; Barron, 1992; Koizumi, 1985, 1986). The interval centered around 3.0 Ma was an extremely warm interval and the Subarctic Front shifted further to the north than its present location prior to the onset of significant Northern Hemisphere glaciation at 2.6 Ma, the newly recognized base of the Quaternary Period (Head et al., 2008). During the interval between 2.8 and 2.4 Ma, diatom assemblages fluctuated, with cold peaks dated at 2.75, 2.6, and 2.45 Ma indicating the drastic north-to-south shift of the Front. Another warm interval is recognized about 2.3 Ma until 2.45 Ma. Diatom accumulation rates declined sharply due to the increase of terrigenous components, resulting from rapid cooling and the global fall of sea level after about 2.7 Ma in the northeast Pacific Ocean (Barron, 1998; Maruyama, 2000). High diatom productivity shifted toward the northwest Pacific Ocean and became higher by enhanced upwelling along the coastal regions. During the interval of 2.7–2.4 Ma, the diatom assemblages dominated by *Coscinodiscus marginatus* Ehrenberg and *N. kamtschatica* rapidly and drastically shifted to one rich in *Neodenticula* complex, *N. koizumi* + *N. seminae*, due to changes in paleoceanographic conditions in the subarctic region (Shimada et al., 2009).

Acknowledgments

I acknowledge with thanks Dr. John A. Barron of the U.S. Geological Survey at Menlo Park for his critical reviews and improvements of English, and Dr. Vivienne Jones of the University College London for her reviews and editorial work.

Introduction

Polar seas are characterized by the presence of multiyear and annually formed sea ice which contributes considerably to the reduction of heat and gas exchange between the atmosphere and the upper layers of the ocean. The enhanced albedo of sea ice relative to the open ocean results in a dramatic reduction of solar radiation at the sea surface, an effect that is further enhanced when the sea ice is snow covered. In either case, the resulting insulation strongly influences changes in climate, both locally and globally. Further, during melting, the outflow of low-salinity surface water affects the climate by influencing deep oceanic circulation. The rapid and significant changes to sea ice extent and thickness in the Arctic and Antarctic in recent decades has stimulated a significant amount of new research into the likely impacts this will have on the future climate of the Earth and the complex ecosystems of the polar regions. At the base of the food chain, sea ice provides a physical support for the development and growth of a productive community of ice algae and a wide diversity of heterotrophic eukaryotes, all of which interact with the underlying surface waters (Caron and Gast, 2010; Róžańska et al., 2009).

Sea Ice Biota

Within sea ice, three distinct habitats can be distinguished mainly according to the position of autotrophic and heterotrophic eukaryotes within the ice matrix: the surface community, the interior community, and the bottom community (Horner et al., 1992) (Note: Prokaryotes are also present in sea ice but these are not discussed here). Surface communities occur at the snow–ice interface resulting from the flooding of the ice surface with seawater, while interior communities correspond to a remnant assemblage of the previous bloom season. The bottom community develops during the spring in the lowest ice layer or at the interface with the ocean. The biota within this bottom ice is further divided into interstitial and sub-ice communities; the latter consisting of algae, such as the Arctic centric diatom *Melosira arctica* Dickie, which floats beneath, or is attached to, the underside of the ice-forming mats and decimeter-long strands (Ambrose et al., 2005). Interstitial communities occur in the bottom 10 cm of annually formed sea ice and are usually associated with small ice crystals, brine pockets, and a well-developed network of channels and capillaries (Arrigo et al., 2010; Horner et al., 1992). This colonization of diatoms in the lower section of annually formed sea ice can be clearly observed in the intense coloration of these layers in cored samples, especially during the spring bloom (Figure 1).

The growth, production, and biomass of the bottom ice algal communities are, in part, controlled by the thickness of sea ice and snow cover, which deeply affect the amount of transmitted light through the ice matrix (Arrigo et al., 2010), and by the availability of macronutrients present in the underlying surface waters (Róžańska et al., 2009). Gosselin et al. (1997) estimated the contribution of sea ice algae to the total primary production to be in the region of 57% in the central Arctic Ocean, while Legendre et al. (1992) reported values between 3% and 25% for the Arctic shelves. Ice algae constitute the main food source for ice-associated and pelagic herbivorous protists (Michel et al., 2002) and metazoans (Nozais et al., 2001), and contribute significantly to carbon cycling throughout the Arctic regions (Michel et al., 2006). Ice algal blooms usually occur before the phytoplankton bloom (Arrigo et al., 2010).

Several names have been used to describe organisms living in close association with the sea ice, but Horner et al. (1992) proposed the term *sympagic community* to describe the group of autotrophic and heterotrophic unicellular eukaryotes that inhabit the ice. In terms of abundance, the main groups of bottom ice eukaryotes are diatoms, flagellates, and dinoflagellates. While diatoms are mainly photosynthetic, a large fraction of the flagellated community, including some dinoflagellates, can be heterotrophic (i.e., feeding on other organisms). Arctic bottom ice algal communities are mainly represented by colonial and solitary pennate diatoms during the bloom period (Róžańska et al., 2009). Among the colonial pennate diatoms, the most abundant and frequently reported species belong to the genera *Entomoneis* Ehrenberg, *Fragilariopsis* Hustedt, *Navicula* Bory, and *Nitzschia* Hassall, while *Nitzschia frigida* Grunow can be considered a key species of bottom ice across all the Arctic regions (Poulin et al., 2011; Róžańska et al., 2009). Solitary pennate diatoms are mainly represented by the genus *Navicula*, followed by a few species of *Nitzschia* and *Pinnularia* Ehrenberg (Poulin, 1990; Róžańska et al., 2009). *Haslea* Simonsen also occurs in low abundance (e.g. *Haslea crucigeroides* (Hustedt) Simonsen, *H. kjellmanii* (Cleve) Simonsen, *H. spicula* (Hickie) Lange-Bertalot and *H. vitrea* (Cleve) Simonsen).

There are approximately 25 recognized species of *Haslea*, mostly reported from tropical and temperate regions, with a few in polar environments. The genus is mainly benthic and mostly present on hard substrates, except for the pelagic *H. wawriakae* (Hustedt) Simonsen. Six species have been reported, though in low abundance, from annually formed sea ice in both the Arctic (*H. crucigeroides*, *H. kjellmanii*, *H. spicula*, *H. vitrea*) (Figure 2) and the Antarctic (*H. trompii* (Cleve) Simonsen, *H. major* (Heiden) Simonsen).

Apart from species identification, investigations into bottom ice eukaryotes have been carried out for a number of

Figure 1 Examples of sea ice coring (left) and bottom ice sections (right) showing the intense brown coloration resulting from the spring diatom bloom, Hudson Bay, Canada, May 2004 (images: M. Poulin).

reasons, including the determination of species distributions across the Arctic (Poulin et al., 2011) and Antarctic, an assessment of the role of sea ice algae within polar food webs and the influence of environmental factors on species

diversity and abundance. In the latter case, the potential for rapid climate change to substantially influence sea ice algae production has provided a strong additional motivation for study.

Analysis of Sea Ice Diatoms

Measurements of algal biomass can be carried out through chemical analysis, while the determination of species abundances and distributions clearly relies on identification of specific taxa (Arrigo et al., 2010). Chemical analysis is most routinely performed by spectrophotometric or fluorometric analysis of chlorophyll *a*, largely since pigment analysis is relatively straightforward and, in addition, can provide a reasonable approximation to organic carbon production (Arrigo et al., 2010). This type of proxy analysis of sea ice autotrophic eukaryotes can also be achieved through the identification and quantification of individual biomarkers. Biomarkers are chemicals that are produced by all biota over a wide range of taxonomic levels. They can represent general classes of chemicals (e.g., lipids and pigments) or, alternatively, correspond to individual molecules. Further, they may be primary or secondary metabolites and are generally identified following isolation from their sources and analysis using a combination of purification and spectroscopic methods such as chromatography and mass spectrometry or nuclear magnetic resonance (NMR) spectroscopy, respectively. Lipids such as fatty acids and sterols are amongst the most common biomarkers to investigate, since they are relatively abundant, common to most organisms and straightforward to analyze and identify.

Diatom Lipids

Fatty acids

Saturated and unsaturated fatty acids are important storage lipids in diatoms and they also help maintain cell fluidity. Cellular concentrations of fatty acids are generally high compared to other lipid classes, whilst in marine diatoms, the saturated compounds are generally more abundant than their polyunsaturated fatty acid counterparts (Volkman et al., 1998). The distinctive chromatographic and mass spectral characteristics of fatty acids, combined with their relatively high abundances, makes them attractive biomarkers to analyze; although the ubiquity of these lipids can be limiting, particularly if source identification is required. Despite this, some broad classifications of individual fatty acids have been used in the identification of source organisms, with studies carried out on single species and mixed assemblages of phytoplankton and ice algae showing that C₁₄, C_{16:1ω7}, C₁₆, C₁₈, and C_{20:5ω3} fatty acids are representative of marine species (e.g., Volkman et al., 1998). Discriminating between the origin of a sea ice and planktonic diatom for these compounds is not really possible, although changes in fatty acid distributions have been used to infer events such as algal blooms (e.g., Reuss and Poulsen, 2002).

Sterols

A second group of biomarkers that are commonly used to monitor primary productivity in the ocean and sea ice are sterols (Volkman et al., 1998). Phytosterols are abundant and important structural constituents of the cell membranes of terrestrial and marine plants (Barenholz, 2002), including microalgae such as diatoms, which mainly contain sterols with between 27 and 29 carbon atoms. In an analysis of 14

species of marine diatoms, a range of sterol distributions was observed, although none were considered to be specific to diatoms (Barrett et al., 1995). Although the nonspecific nature of sterols limits detailed determination of source organisms, the analysis of sterols, like that of fatty acids, can still be useful with respect to the measurement of primary productivity.

Highly branched isoprenoid alkenes

A third class of biomarker chemical produced by some diatoms are simple nonfunctionalized lipids known as highly branched isoprenoid (HBI) alkenes which, unlike fatty acids and sterols, are restricted in terms of their sources, making them highly suitable chemicals to be analyzed as biomarkers. HBIs were first reported in the 1970s following isolation from sediments worldwide, although the precise structures of these chemicals were unknown then. As part of a wider investigation into diatom lipids, Volkman et al. (1994) were the first to show that HBIs are made by diatoms, with C₂₅ and C₃₀ HBIs produced by *H. ostrearia* (Gaillon) Simonsen and *Rhizosolenia setigera* Brightwell, respectively. Since this initial identification, a number of further HBI-producing diatoms have been identified, including other *Haslea* spp., *Navicula* spp., and *Pleurosigma* spp. (e.g., Belt et al., 2000; Massé, 2003). The structures of numerous HBI alkenes have been determined through large-scale culturing of individual diatom species, bulk lipid extraction, purification of individual compounds and analysis by ¹H and ¹³C NMR spectroscopy (e.g., Belt et al., 1996, 2000; Massé, 2003). As a result, more than 20 individual structures of C₂₅ and C₃₀ HBI alkenes have been reported, together with some related monocyclic compounds (Massé, 2003). C₂₅ and C₃₀ HBIs occur with varying degrees of unsaturation and in different isomeric forms (see Figure 3 for typical HBI structures and numbering scheme used throughout the remainder of the text).

The majority of C₂₅ HBIs isolated from diatoms range in unsaturation from 2 to 5, although more polyunsaturated compounds have also been reported. The positions and stereochemistries of the double bonds are controlled by the biosynthetic mechanisms responsible for their formation and each of these structural features exhibits some variability. For example, while a double bond at the terminal (vinyl) position is present in virtually all C₂₅ and C₃₀ HBI alkenes, the variability in the positions of the other double bonds leads to regioisomerism, with greater unsaturation resulting in the largest number of regioisomers. Thus, while the structures of only two diene isomers (2,3) have been characterized from diatoms, numerous tetraenes (e.g., 7,8) have been reported, following isolation from large-scale cultures. The presence of both unsaturation and chiral centers in C₂₅ and C₃₀ HBIs can potentially result in stereoisomerism in these compounds and this is indeed observed. In most cases, the stereochemistries of the trisubstituted double bonds in HBIs have the *E* configuration as is common for simple biogenic lipids of this type. However, there are exceptions to this general observation, with both C₂₅ and C₃₀ compounds exhibiting *E* and *Z* isomerism from *Pleurosigma intermedium* W. Smith (5,6) and *R. setigera* (10,11), respectively (Belt et al., 2000, 2001). Some variability in the stereochemistries of the chiral or asymmetric centers in HBIs has also been reported although, to date, this kind of investigation has not been carried out for most HBIs. The reasons for the observed

Figure 3 Representative structures and numbering scheme of C_{25} and C_{30} highly branched isoprenoid alkene biomarkers cited in the text.

variability in both regio- and stereoisomerism is, as yet, unknown, but probably relates to the functions of these lipids which are not well understood. What is clear, however, is that both the mevalonate and methylerythritol phosphate isoprenoid biosynthetic mechanisms are responsible for the formation of HBIs, which probably reflects the different locations and roles of these biomarkers in diatom cells (Massé, 2003).

The existence of C_{25} and C_{30} HBIs in different structural and isomeric forms provides a potential association between structure and source, especially as the formation of C_{30} HBIs (and their monocyclic analogs) appears to be restricted to biosynthesis by *R. setigera* (Belt et al., 2001; Volkman et al., 1994). For the C_{25} HBIs, isomers containing double bonds in either of the C5–C6 or C6–C17 positions (e.g., 2–4, 7–9) are common for *Haslea* spp. and *Navicula* spp. (Belt et al., 1996, 2000; Massé, 2003), while *Pleurosigma* spp. are responsible for biosynthesis of isomers with double bonds in the C7–C20 position (e.g. 5,6; Belt et al., 2000). However, these source–structure relationships are not exclusive since, for example, *R. setigera* also produces C_{25} HBI alkenes with C7–C20 double bonds, albeit only at specific intervals within its life cycle (Massé, 2003). It is also clear that variability in distributions of HBIs also exists across different populations of the same species. Several studies have attempted to investigate this, largely by culturing single species under a range of phenotypic conditions including light, salinity, and temperature (Massé, 2003; Rowland et al., 2001). In the case of *H. ostrearia*, salinity was found not to significantly influence either production or distribution of C_{25} HBIs although light intensity was shown to have some control over lipid production, as expected (Massé, 2003).

To date, however, most studies have resulted in few definitive outcomes, but it seems likely that controls on HBI

distributions are not simply limited to growth conditions, but depend on the source organism concerned, as well as other factors. For example, in the case of *R. setigera*, distributions of C_{25} and C_{30} HBIs have been shown to be strongly dependent on the physiological state of the diatoms within their life cycle, with C_{25} HBIs produced mainly during the auxospore phase (Massé, 2003).

The most striking influence on C_{25} HBI distribution in *H. ostrearia* has been shown to be growth temperature (Rowland et al., 2001). In most cultures, *H. ostrearia* produces C_{25} HBIs with unsaturation ranging from 2 to 5. Significantly, when *H. ostrearia* was cultured over a range of temperatures, it was found that the more unsaturated isomers had the greatest abundances at the higher growth temperatures, while the relatively saturated compounds had the greatest concentrations at lower temperatures (Rowland et al., 2001). Thus, at 25 °C, the most abundant isomers were tetraenes and pentaenes, while at 5 °C, only dienes were present. At intermediate temperatures (e.g., 15 °C), trienes were the most abundant HBIs, although all isomers were present to some extent. *H. ostrearia* failed to grow under more extreme conditions (e.g., below 5 °C or above 30 °C) preventing further examination of the temperature influence on isomer distribution.

IP₂₅: A Proxy for Arctic Sea Ice

Structure and Properties of IP₂₅

The clear temperature influence on C_{25} HBI distributions from 5 to 25 °C observed for *H. ostrearia* (Rowland et al., 2001) prompted Belt et al. (2007) to hypothesize that some polar sea ice diatoms may be capable of producing relatively

saturated C₂₅ HBI isomers, especially as some *Haslea* spp. had previously been reported in Arctic and Antarctic diatom communities, even if such species were only present as relatively minor constituents (Poulin, 1990). In addition, it was further suggested that these relatively saturated sea ice-derived isomers could have the potential to serve as proxies for past sea ice occurrence when detected in dated marine sediments in the polar regions, especially as they would probably be more stable in sediments than their polyunsaturated counterparts (Belt et al., 2007).

In order to further test these hypotheses, Belt et al. (2007) sampled and analyzed sea ice from three regions of the Canadian Arctic during the spring algal bloom period. In each case, *Haslea* spp. were detected in the bottom sections of the sea ice cores, together with several C₂₅ HBIs previously reported (Belt et al., 2007). In addition to the presence of a C₂₅ diene (2) as expected, a previously unreported monounsaturated isomer (1) was also detected. The structure of this novel biomarker was established by synthesis from the related diene and characterization by ¹H and ¹³C NMR spectroscopy. Following the structural elucidation of this monounsaturated compound, chromatographic and mass spectral analysis showed it to be different from that of other C₂₅ HBI monoenes previously reported. As a result, the term IP₂₅ (ice proxy with 25 carbon atoms) was proposed for this monounsaturated C₂₅ HBI biomarker (1).

As part of this initial investigation into the potential for IP₂₅ to be used as a proxy for past Arctic sea ice occurrence, Belt et al. (2007) also sampled surface sediment material from the Canadian Arctic Archipelago (CAA) and sub-Arctic regions and found IP₂₅ to be present in all cases, thus providing evidence for efficient transfer of this biomarker from the sea ice to underlying sediments. IP₂₅ was also detected from older sediments radiocarbon dated at ca. 9000 years old and its stable isotopic composition (δ¹³C) was later shown to be consistent with a sea ice origin (Belt et al., 2008).

Paleo Arctic Sea Ice Reconstruction Using IP₂₅

Although a number of proxies have been used to infer past environmental or climatic conditions on Earth, it is clearly important to understand the limitations of individual proxies, in order for their measurements to be fully evaluated and correctly interpreted. In general, proxies rely to a large extent on various forms of calibration, with the added assumption that recent observations are representative of conditions in the past. In the case of the sea ice biomarker proxy IP₂₅, strict calibrations between sedimentary abundances and associated sea ice conditions have not yet been carried out, partly as a result of a paucity of well-defined or accurate recent sea ice conditions, both temporally and spatially. Despite this, some meaningful interpretations of the abundances of IP₂₅ have been made through comparisons of sedimentary concentrations and fluxes with historical records of sea ice in different Arctic regions.

Initially, Massé et al. (2008) determined the concentrations of IP₂₅ in a marine sediment core (MD99–2275) obtained from the North Icelandic Shelf and compared these findings with known sea ice occurrence and other climate conditions documented in historical records covering the last 1000 years.

This study demonstrated a number of strong correlations between the sedimentary concentrations of IP₂₅ and documented climate conditions, particularly during cold intervals, including those in which extensive sea ice cover had been reported. Good agreement between biotic proxies was observed between the sea ice biomarker data (IP₂₅) and an independent sea surface temperature reconstruction using a diatom-based transfer function (Figure 4). Thus, on a centennial scale, sedimentary IP₂₅ concentrations were at their highest during the seventeenth and nineteenth centuries, previously reported as the coldest centuries of the last millennium in the Northern Hemisphere (Jones et al., 2001). At a higher temporal resolution, IP₂₅ abundances were greatest during decades considered to represent either extremely cold intervals (e.g., AD 1690–1700) or intervals when extensive sea ice cover had been well documented. This study by Massé et al. (2008) also provided proxy evidence for sea ice conditions for intervals when historical records were absent. The absence of such records might be explained by few people visiting in periods of severe weather. Further, observations of, consecutively, lower and higher IP₂₅ concentrations during the first and second half of this 1000-year study period were consistent with the occurrence of the well-known Medieval Warm Period (MWP) and Little Ice Age (LIA) epochs.

A subsequent investigation of a second sediment core from the North Icelandic Shelf (MD99–2263), obtained from a more westerly location, revealed very similar outcomes, as would be expected given the position of the Polar Front around northern Iceland during the last millennium. In contrast, and importantly from a calibration point of view, analysis of a sediment core from southwest Iceland showed that IP₂₅ was absent from all sediment horizons, consistent with this location being south of the Polar Front and free of sea ice during the study interval (Andrews et al., 2009).

A second study aimed at calibrating the IP₂₅ proxy was carried out by Vare et al. (2010) who analyzed sediment samples from three locations in the Barents Sea for which historical sea ice records existed for the last few hundred years, principally as a result of old whaling records and more recent observational accounts made through aerial reconnaissance. In this case, study locations were chosen to represent periods of continuous, variable or sea ice-free conditions, especially during the summer. Consistent with the observational records, IP₂₅ abundances and fluxes in cores obtained from the north and southeast regions of the Barents Sea demonstrated periods of frequent sea ice occurrence during the last two centuries, with greater variability for the more southeasterly location. In contrast, for the study location in the southwest Barents Sea, the absence of IP₂₅ from all sedimentary horizons covering the last ca. 300 years was consistent with the failure of sea ice to encroach into this region in recent centuries.

These two sets of proxy-based investigations into sea ice occurrence around Iceland and the Barents Sea during the last millennium have, therefore, provided reasonable evidence that sedimentary abundances of the IP₂₅ biomarker can be used to provide at least qualitative (e.g., presence/absence) paleo-sea ice reconstructions for the Arctic. As a result, new paleo-sea ice investigations are being conducted over timescales that precede historical records and for regions of the Arctic where previous records are incomplete, absent, or for which existing proxy data are contradictory.

Figure 4 Relative abundances of IP_{25} found in the core MD99-2275 for the period AD 800–1950 plotted against historical records of Icelandic sea ice interpreted from Ogilvie (1992) and Ogilvie and Jónsson (2001) (bottom scales) and diatom-based reconstructed sea surface temperature (Jiang et al., 2005). Reproduced from Massé G, Rowland SJ, Sicre M-A, Jacob J, Jansen E, and Belt ST (2008) Abrupt climate changes for Iceland during the last millennium: Evidence from high resolution sea ice reconstructions. *Earth and Planetary Science Letters* 269: 565–569. Copyright Elsevier.

The CAA contains a vast array of islands and channels that connect the Arctic Ocean with the Pacific and Atlantic oceans, yet, until recently, relatively little was known about the sea ice record of this key oceanographic region other than what has been inferred from neighboring terrestrial records or other components of the marine record (e.g., water masses). In modern times, the CAA is characterized by frozen channels during the winter months following the onset of sea ice formation during the late autumn. Sea ice melt is variable throughout the channels, making navigation possible but often hazardous. In the longer term past, sea ice occurrence has almost certainly been more severe, at least in recent centuries, blocking the Northwest Passage. Following collection of several marine sediment cores during the 2005 ArcticNet oceanographic campaign through the CAA, paleo-sea ice records covering the Holocene have been constructed, based mainly on the variable occurrence of IP_{25} (Belt et al., 2010; Vare et al., 2009; Figure 5).

Initially, Vare et al. (2009) interpreted the variable abundance of IP_{25} in a core obtained from Barrow Strait as representing changes in sea ice conditions throughout the Holocene for this region. This study revealed a number of key outcomes, previously unknown for this important region. Firstly, radiocarbon dating of the core demonstrated that it covered the entire Holocene epoch or the last 10 000 years. This chronological analysis also revealed some variations in the sedimentation rate within the core, which are likely to be a result of changes in local climate. Importantly, the IP_{25} biomarker was present in each of the 650 horizons analyzed, providing evidence for the presence of at least partial sea ice conditions on a decadal to semicentennial timescale throughout the

Holocene. Given the variability in sedimentation rates, Vare et al. (2009) converted all sedimentary IP_{25} concentrations to annual fluxes in order to facilitate more meaningful and consistent temporal comparisons (Figure 6). IP_{25} fluxes were consistent and relatively low during the early and mid-Holocene, before increasing around 3000–4000 years before present (BP), after which they remained high but with much greater variation compared to the early Holocene. These observations were interpreted as indicating reduced sea ice cover in the early to mid-Holocene, with more extensive sea ice cover after ca. 3000 years BP. The co-occurrence of a related HBI diene with an extremely similar flux profile provided complementary evidence for such changes in climate, especially as the proportion of the more unsaturated HBI diene decreased after ca. 3000 years BP, in line with the previously reported temperature dependence of HBI distributions on growth temperature (Rowland et al., 2001). Further, the occurrence of significant changes to sea ice conditions throughout the Holocene, especially around 3000 years BP, was consistent with trends in the extent of melt from the Agassiz ice cap (north of Barrow Strait) and with other proxy evidence for the termination of the so-called Holocene Thermal Maximum during the second half of the Holocene.

In a subsequent study, Belt et al. (2010) constructed paleo-sea ice records for Victoria Strait and Dease Strait, also within the CAA, based on the occurrence of IP_{25} (Figure 6). This study aimed to identify any consistencies or differences in the spatial and temporal distribution of spring sea ice within the CAA throughout the Holocene. The two examined cores did not cover as much of the Holocene as the cores from the Barrow

Figure 5 Map of the Canadian Arctic Archipelago and the sampling locations (ARC-3,4,5) described in Vare et al. (2009) and Belt et al. (2010). Reproduced from Belt ST, Vare LL, Massé G, et al. (2010) Striking similarities in temporal changes to spring sea ice occurrence across the central Canadian Arctic Archipelago over the last 7000 years. *Quaternary Science Reviews* 29: 3489–3504. Copyright Elsevier.

Strait study, especially in the early part of the epoch, but some interesting comparisons between all three study locations were nonetheless made. Most significantly, the sea ice biomarker IP₂₅ was again present in all of the horizons examined from the Victoria Strait and Dease Strait cores, consistent with the observations made previously for Barrow Strait (Vare et al., 2009). The IP₂₅ fluxes were also quite variable, but lowest in the mid-Holocene, before increasing at ca. 3000 years BP, suggesting some similarity in sea ice conditions between the three locations. Indeed, statistical analysis of the IP₂₅ fluxes demonstrated significant correlations between sites, especially in the early and mid-Holocene (Belt et al., 2010). However, in contrast to the data reported for Barrow Strait, the IP₂₅ fluxes decreased from their maximum values at ca. 3000 years BP during a relatively brief (500–1000 years) interval around 1000 years BP, indicative of lower sea ice occurrence. Belt et al. (2010) noted that this coincided with a period of warmer climate in the more southerly locations as predicted from terrestrial proxy studies and from the documented migration of ancestral Inuit peoples.

The measurement of IP₂₅ in marine sediments to determine past Arctic sea ice conditions has recently been extended to other regions of the Arctic and for longer timescales. Fram Strait represents a major Arctic gateway that connects the Arctic and Atlantic oceans and channels temperate water from the North Atlantic along the western continental margin of Spitsbergen. In contrast, cold water and sea ice are transported south through Fram Strait via the East Greenland current. By analyzing for IP₂₅ and another biomarker, brassicasterol, derived from open water phytoplankton, Müller et al. (2009) established a 30 000-year sea ice record for Fram Strait. Perhaps of greatest significance, Müller et al. (2009) used the combination of the two biomarkers to highlight the occurrence of perennial ice, and ice-free conditions as representing extremes in climatic conditions, together with evidence for spring sea ice occurrence, mainly through the IP₂₅ biomarker. This study also illustrated the potential for this biomarker-based approach to distinguish between more subtle changes in sea ice conditions,

such as those associated with a regular or variable spring ice edge.

Refining the IP₂₅ Sea Ice Proxy and Future Directions

Collectively, this relatively small number of case study determinations of paleo-sea ice conditions in the Arctic has nonetheless shown the potential to use IP₂₅ to obtain meaningful datasets that can be interpreted alongside other proxy records to establish paleoclimate records. In order to improve on the scope and accuracy of these reconstructions, it will be necessary to further investigate the nuances of the IP₂₅ biomarker proxy, particularly with respect to interpretation of quantitative data and a move toward an increased understanding of how the presence of IP₂₅ in sediments may be influenced by other environmental or climatic factors. For example, it will be important to establish whether sedimentary abundances or fluxes of IP₂₅ can be calibrated so as to yield more quantitative assessments of sea ice occurrence, ice type or thickness. In addition, since sedimentation rates in the Arctic are typically on the order of tens of years per cm (at best), determining interannual variations is probably beyond the scope of the IP₂₅ proxy. However, having a greater insight into the production of IP₂₅ by sea ice diatoms in the first place may help interpret sedimentary distributions, even at these lower resolutions. With this in mind, Brown et al. (2011) investigated the time interval over which IP₂₅ was present in Arctic sea ice by sampling sea ice cores collected from the southeast Beaufort Sea from late winter through to the ice melt in late spring/early summer. This study showed that the IP₂₅ content of the sea ice was absent or below the limit of detection during the winter period as expected, before increasing during the early spring and reaching a maximum concentration during May, coincident with the spring algal bloom as evidenced from parallel cell abundance and pigment determinations. This investigation demonstrated the strong seasonal influence on IP₂₅ production, with the majority (~90%) of this biomarker being

Figure 6 IP_{25} flux profiles (value – median) for ARC-3 (Barrow Strait), ARC-4 (Victoria Strait) and ARC-5 (Dease Strait). Reproduced from Belt ST, Vare LL, Massé G, et al. produced in a relatively short (4–6 weeks) time interval during the spring (Brown et al., 2011).

Previously, a strict sea ice diatom origin for IP_{25} had been proposed on the basis of its presence in bulk Arctic sea ice samples, its absence from phytoplankton collected under open water conditions from nearby locations, and its distinctive stable isotopic composition in sea ice, in sediment trap material and in sediments (Belt et al., 2007, 2008). In their more recent and detailed study looking at sectioned sea ice cores, Brown et al. (2011) also showed that the IP_{25} biomarker was largely restricted to intervals of the sea ice cores that had brine volume fractions capable of supporting colonization and growth of diatoms (>5%; Golden et al., 2007) and that the highest IP_{25} concentrations were found in sections of sea ice distal to the ice–seawater interface; both of these observations are consistent with the production of IP_{25} by sea ice-associated diatoms.

In summary, Arctic sea ice diatoms produce a suite of biomarker chemicals that are straightforward to identify and quantify by routine analytical methods. The analysis of fatty acids and sterols is somewhat limited to determinations of primary production since they occur too commonly in other organisms to permit more targeted measures, such as source identification. In contrast, HBI alkenes are biosynthesized by a limited number of diatoms and can, therefore, be used to identify sources when detected in the marine environment, including sediments. One such monounsaturated HBI alkene, IP_{25} , is biosynthesized exclusively by Arctic sea ice diatoms and the presence of IP_{25} in well-dated marine sediments is proving extremely valuable in determining paleo-sea ice records across the Arctic. To date, IP_{25} has not been detected in Antarctic diatoms or sediments, although it is feasible that other HBI compounds may have the potential to be used as paleo-sea ice and climate proxies.

Glossary

Cold-climate environment: Includes periglacial environments, where the mean annual air temperature is less than +3 °C, as well as regions with snowy climates, where the coldest mean monthly temperature is below −3 °C.

High-latitude dune fields: Sand dunes found in more northerly and southerly latitudes and typically associated with seasonal cold-climate conditions.

Parabolic dunes: A dune in the shape of a parabola or horseshoe, in plan view, with a concave windward slope and a convex leeward slope. The trailing arms of parabolic dunes are commonly vegetated.

Sand dunes: Distinct constructional eolian landforms that generally exceed several meters in height and exhibit slipfaces. They typically comprise stacked cosets of large-scale, high-angle cross strata, representing net deposition from climbing bedforms.

Sand sheets: A landform composed of eolian sand of varying thickness but without pronounced relief typically with subhorizontal to low-angle cross-stratification formed by the migration of low-amplitude wind ripples or by sedimentation in the presence of vegetation. The cover sands of the European sand belt are an extensive area of sand sheet deposits.

Introduction

Quaternary dune fields are widespread throughout high-latitude regions of the Northern Hemisphere including Canada, Alaska, Europe, and Russia. Much of North America north of approximately 45° N latitude, and Europe north of 50° N latitude, was glaciated during the late Quaternary (Wisconsin and Weichselian glacial period, respectively). Most of these areas also presently experience seasonal cold-climate conditions, though there are few large dune fields active today. Cold-climate eolian conditions presently occur in Antarctica, though the few dune fields there are small.

Dune activity is largely controlled by a combination of the three interacting factors of transport capacity (i.e., windiness), sediment supply, and sediment availability. Sediment supply represents the total amount of sandy source material, whereas sediment availability represents the proportion of unprotected, sandy material, that is, that available for transport, and may be reduced by vegetation cover, moisture, snow, ice, surface lag deposits, and other factors. In high latitudes, sediment supply appears to be the limiting factor on the size of dune fields. Individual dune fields in high latitudes are rarely larger than a few 100 km²,

owing to the relatively small amount of sediment. In comparison, sediment availability, as influenced by the amount of vegetation cover, appears to be a significant control on the degree of dune activity in high latitudes. Transport capacity is also a factor, as high-latitude continental areas may have been windier during Late Glacial and early Holocene times than they are today.

Primary Dune Fields

North America

Dune fields occur throughout Canada (about 26 000 km²) and the northern contiguous USA (Figure 1). The majority of dune fields (about 90%) are in central Canada owing to the availability of suitable sandy sediments and strong postglacial winds. The Athabasca Sand Dunes of northern Alberta and Saskatchewan is the largest dune field in Canada (4800 km²), and it contains the largest area of active dunes (385 km²) in the high latitudes (Figure 2). Other large dune fields include the Wood Buffalo Sand Hills, Brandon Sand Hills, Great Sand Hills, and Minot Sand Hills (Figure 1), though they contain only limited areas of active dunes.

Figure 1 High-latitude dune fields of northern North America. Distribution of dune fields shown in relation to the maximum late Wisconsin glacial ice extent between 18.0 and 15.5 ka BP, and to later ice extents at 11.0 and 8.0 ka BP (uncalibrated radiocarbon years).

Eolian dune fields and sheet sands are also widespread in Alaska (Figure 1), occurring within all major lowlands and alluvial plains beyond the limit of the last glaciation. The most notable dune field is the Great Kobuk Sand Dunes of north-western Alaska (650 km²), which contains areas of active dunes (Figure 3).

Europe and Russia

Eolian sand deposits form a continuous belt that extends through north-west, central, and east Europe, known as the European sand belt (Figure 4). Stabilized dune fields are found inland or along river systems in the UK, Belgium, The Netherlands, Germany, Poland, Belarus, Ukraine, Lithuania,

Figure 2 Active transverse dunes in the Athabasca sand dunes, northern Saskatchewan, Canada (photograph by D.G. Smith).

Figure 3 Large active dune area, approximately 17 km long, of The Great Kobuk Sand Dunes, Alaska (NASA Alaska High Altitude Aerial Photography, courtesy of the Geophysical Institute, University of Alaska Fairbanks).

Latvia, Estonia, and the Russian Plain of European Russia. In addition, relatively small but widespread dune fields are scattered throughout Norway, Sweden, and Finland (Fennoscandia; Figure 5), north of the Arctic Circle.

Other Dunes and Dune Fields

Small active dune fields occur in Antarctica, most notably in the ice-free Victoria Valley of southern Victoria Land. This dune field is about 3.5 km long and <1 km wide and consists of sand sheets, and single and compound barchanoid dunes forming transverse ridges between 70 and 600 m long (Figure 6). Other dunes described as ‘whalebacks’ occur without slipfaces and mantle underlying ground moraine. The dunes contain interbedded snow and sand, and are underlain by permafrost. In addition to inland dunes, active coastal dunes occur in high-latitude, cold-climate, and temperate regions along sandy shorelines in areas of moderate-to-high wind regimes. Active high-latitude marine coastal dunes are found in Europe, Alaska, and the Beaufort Sea, Atlantic and Pacific coasts of Canada. Stabilized coastal dunes also occur inland of present-day marine and lake shorelines due to a decline in relative sea level as a result of isostatic uplift or drainage of postglacial lakes during the late Quaternary and Holocene. These raised, stabilized coastal dunes may be used to document the timing of former higher lake and sea levels.

Types

The most common dune type in high latitudes is the parabolic dune, both simple and compound forms. Parabolic dunes are indicative of moist sand and vegetation, which modify sediment availability and transport. Most high-latitude parabolic dunes typically have partially vegetated heads with lee side slipfaces that are convex downwind in plan view, and trailing arms that are partially or completely vegetated (Figure 7).

Transverse and longitudinal dunes may also occur in high-latitude areas, though some ‘longitudinal’ dunes actually represent the remnant arms of parabolic dunes. Barchanoid dunes are found in some cold arid regions due to the absence of vegetation and moisture. Blowouts are common where vegetation cover on dune fields is high, and often modify stabilized dunes. Many temperate and cold-climate dune fields of high latitudes are presently stabilized by vegetation, suggesting that they are formed under climatic regimes different from those of today.

Although most high-latitude dunes are inactive, they are presently active in some areas of Europe and North America. Small portions of dune fields on the northern Great Plains of North America are active due to moderate-to-strong wind regimes, and periodic droughts that reduce vegetation cover. More northerly dune fields such as the Kobuk and Athabasca dune fields may be active today due to a combination of factors including moderate present-day wind regimes, moisture stress, and limited growing seasons, and periodic sediment input from rivers, deltas, or lakeshores. Along eastern Hudson Bay, Canada, and in the Lapland region of Finland, small dune areas in subarctic settings are active due to disturbance by fire, and overgrazing and trampling by reindeer, respectively.

North America

Most dune fields in Canada and the northern contiguous USA consist of parabolic dunes and blowouts, with a few dune fields also containing transverse and longitudinal dunes. Various forms of parabolic dunes occur. In northern Canada, very elongate and narrow stabilized parabolic dunes occur on otherwise bare rock of the Canadian Shield (Figure 8). These dunes are typically <10 m high, but with trailing arms up to

Figure 6 Active transverse dunes of the Victoria Valley, Antarctica (photograph by N. Lancaster).

Figure 7 Active parabolic dune in southwestern Saskatchewan, Canada. Dominant transporting winds are from left to right. The head of the dune is partially vegetated whereas the trailing upwind arms are stabilized by vegetation (photograph by S.A. Wolfe).

Figure 8 Stabilized elongate parabolic dunes of northern Saskatchewan, Canada. Dune at center left is approximately 3 km long and is oriented towards the northwest. The dunes have migrated over bedrock surfaces with low-sediment supplies. Transporting winds were from the southeast, indicating that anticyclonic winds associated with the Laurentide Ice Sheet were responsible for their formation. See text and **Figure 12** for details (National Air Photo Library of Canada photograph A13385-97).

Figure 9 A field of densely concentrated, stabilized circular parabolic dunes, Great Sand Hills, southwestern Saskatchewan, Canada. These dunes were active in the 1800s, possibly as a result of drought in the late 1700s (Wolfe et al., 2001; photograph by S.A. Wolfe).

8 km long. In southwestern Saskatchewan, parabolic dunes tend to be more densely concentrated and less elongate (**Figure 9**). The Athabasca Sand Dunes contain a wide variety of active dunes, including parabolic, transverse (**Figure 2**), and 'hybrid' transverse-longitudinal dunes. Well-formed stabilized transverse dunes up to 25 m high also occur in the Holmes Crossing sand hills of central Alberta, Canada (**Figure 10**). Many dune fields in the northern Great Plains of Canada and the USA are modified by blowouts that have been active at varying times due to drought and disturbance.

Dune fields in Alaska include stabilized parabolic, longitudinal, and compound dunes, ranging from 1.5 to 60 m high. Active dunes in the Kobuk Valley and Koyukuk Flats include

Figure 10 Stabilized transverse dunes, Holmes Crossing, central Alberta, Canada. Optical dating indicates these dunes were last active approximately 15 000 years ago. Transporting winds were from the northwest (upper left), and image view is 7 km wide (National Air Photo Library of Canada photograph A25853-51).

transverse and barchanoid dunes (**Figure 3**). Other areas include partially stabilized parabolic and blowout dunes, and rounded hillocks and hollows or broad undulating ridges and swales with no distinct dune type.

Europe and Russia

Stabilized dune fields occur on the northern portions of the European sand belt. In the United Kingdom, the dunes are typically low hummocks; in The Netherlands, they are low ridges of parabolic form; in Germany, parabolic dunes are typically only a few meters high, and up to 12 m; and in Poland, parabolic, longitudinal, transverse, and, rarely, barchanoid dunes occur. Present-day eolian activity in Europe is mostly restricted to areas of human or animal disturbances.

Dune fields on the Russian Plain include individual and compound parabolic dunes, transverse dunes, and blowouts, and may also be associated with sand sheets. Dune heights typically range from 1.5 to 10.0 m, and may reach 20.0 m. Some parabolic dunes are several kilometers long.

Stabilized parabolic dunes are common in Fennoscandia, and may occur in clusters that are also parabolic in form (**Figure 11**). Individual dunes are typically <1300 m long, up to 150 m wide, and up to 12 m high, but more commonly 4–6 m high. Active parabolic dunes are found in only a few locations, although active blowouts on stabilized dunes are relatively common beyond the treeline.

Origins

The origins of high-latitude dune fields are tied to the interrelated factors of sediment supply, sediment availability, and wind regime. Many dune fields of high latitudes are derived from localized sandy sediments of fluvial, lacustrine, or glacial origin that were deposited by glacial meltwater. Typical source areas include flood plains, glacial outwash plains, braided river valleys, deltas, lake shorelines, eskers, kames, and some till plains and moraines. The size of most high-latitude dune fields is ultimately controlled by the amount of sandy sediment in

Figure 11 Active and stabilized parabolic dunes and blowouts at Melajärvi (Paddle Lake), in northern Finland. The source material for the dunes is an esker ridge and surrounding glaciolacustrine/deltaic sediments. The largest dune is about 550 m across and the effective wind direction is from the west-northwest. The area is north of the coniferous treeline, and the surface is vegetated by mountain birch (*Betula pubescens*) dwarf shrubs and lichens (Topographic Division of the Finnish Defense Forces, photograph V9120/111).

these deposits. However, the timing of dune activity is more related to periods when these sandy sediments were available for transport by wind. Within or proximal to formerly glaciated areas, initial dune field construction may have occurred shortly after glacial retreat and deposition of the source sediments, when the sandy terrain was sparsely vegetated. It is also hypothesized that winds during these initial periods of dune construction were stronger than today in parts of northern North America and Europe, due to the proximity of continental ice sheets and their effects on pressure gradients and atmospheric circulation patterns.

Subsequent episodes of dune reactivation during the Holocene may be related to climatic variability, affecting available moisture and vegetation cover, or disturbance by fire, animals, or humans.

North America

Within the glaciated regions of Canada and northern USA, most dune fields are derived from discrete sandy glaciofluvial and glaciolacustrine deposits associated with the retreat of Wisconsin glacial ice. Here, the contrast between relatively small dune fields of formerly glaciated North America and much larger dune fields of unglaciated regions to the south

(e.g., the Nebraska Sand Hills of the central Great Plains, USA) is evident (Figure 1). The largest of these northern dune fields, the Athabasca Sand Dunes, was originally supplied by sandy meltwater-derived sediments deposited into glacial Lake Athabasca during the retreat of the Laurentide Ice Sheet about 9500 calendar years (cal) before present (BP). The dunes have since been supplied by river, delta, and the lakeshore sediments as lake levels declined due, in part, to isostatic rebound.

In the unglaciated lowlands of central and southwestern Alaska, dune fields are derived largely from outwash sediments of major rivers. However, most exposures within these dunes are underlain by subhorizontally stratified sand and subordinate silt, interpreted as eolian sheet sands formed during full-glacial (Wisconsin) conditions. Therefore, the dunes may not have formed from direct reworking of older outwash sediments, but as a result of reworking of eolian sand sheet sediments since the Last Glacial Maximum.

Europe and Russia

Similar to high-latitude dune fields of North America, the European sand belt is closely tied to the extent of glaciation, though the relation is somewhat less distinct. The northerly edges of the sand belt containing most of the dune fields and sand sheets coincides roughly with the maximum position of the late Weichselian ice sheet, whereas finer-grained cover sands and loess approximately coincide with the maximum limit of Pleistocene glaciation (Figure 4). Extensive ice-marginal deposits, such as outwash plains, glaciofluvial, and glaciolacustrine deposits, and abandoned river floodplains and spillways channels supplied sediment for eolian redeposition. Similarly, dune fields on the Russian Plain are located predominantly in areas of outwash plains and meltwater channels, and are derived from glaciofluvial or glaciolacustrine sands. In Fennoscandia, dune fields are evidently derived from glaciofluvial sources, including eskers (Figure 5), kames, deltas, valley trains, ice-dammed lake deposits, and outwash plains.

Ages

High-latitude dune fields throughout much of northern North America and Europe occur within the most recent glacial limits and, therefore, their maximum ages postdate the time of deglaciation. Beyond these limits, dune fields may be older, though it appears that most either originated, or were significantly reworked during the Last Glacial Maximum (late Wisconsin and late Weichselian, respectively). A common problem with determining the age of dune fields is that of partial or complete reworking under conditions of changed climate or disturbance. Thus, reworking may result in superimposed dunes that are potentially misleading indicators of the age and source of the underlying deposits.

North America

The maximum extent of the late Wisconsin glacial ice is the primary factor limiting the age of dune fields in Canada and the northern contiguous USA, as dune fields within this region

must postdate deglaciation. **Figure 1** illustrates the maximum extent of the ice sheet between 18.0 and 15.5 ka BP, along with the ice extent at later times during deglaciation, at about 11.0 and 8.0 ka BP. This shows that the maximum limiting ages of dune fields within the glacial limit are potentially time transgressive.

In accordance with glacial retreat, the oldest dune fields are expected to be located near the maximum extent of the Wisconsin ice sheet. However, most ages of eolian sands and paleosols in northern Great Plains dune fields along the southerly extents of the Laurentide Ice Sheet relate to late Holocene dune activity that may be associated with episodes of increased aridity in relation to drought. Such a difference in expected ages of eolian sediments highlights the issue of reworking of dune fields in high latitudes.

In contrast, stabilized parabolic dunes have been found in northern Saskatchewan (David, 1981), and southern Quebec, Canada (Filion, 1987), indicating postglacial dune activity initiated at about 10 ka BP. Dune activity is interpreted as having occurred under cool, dry conditions, and with dune-building winds coming from anticyclonic air circulation induced by the retreating Laurentide Ice Sheet (**Figure 12**). Dune activity ceased when circulation patterns similar to present were established following continued retreat of the

Figure 12 Map of the ice frontal position in North America, ca. 9.5 ka BP, at the time of initial dune formation in northern Saskatchewan and southern Quebec, Canada. Near the end of the Wisconsin glaciation, the retreating continental glacier controlled the distribution of regional air masses by effectively blocking the southward flow of polar air. Instead, it produced its own gravity airflow that descended radially towards the margins of the ice sheet and was gradually deflected clockwise by the Coriolis force. Upon reaching the ice margin, the dry, cold winds were blowing southwestward in the St. Lawrence Lowlands of Quebec in the east and northwestward in northern Saskatchewan and Alberta in the west, producing correspondingly oriented dunes in these areas. Large arrows show principal airflow directions associated with anticyclonic circulation in relation to the high-pressure center (H) over the Laurentide Ice Sheet. Reproduced from David PP (1981) Stabilized dunes ridges of northern Saskatchewan. *Canadian Journal of Earth Sciences* 18: 286–310.

ice sheet. At both localities, however, activity continued for a short time under modified winds and climate prior to stabilization.

Despite the preceding observations, the oldest recognized late Quaternary dune deposit in Canada is the Kittigazuit Formation of the Tuktoyaktuk Coastlands along the southern Beaufort Sea, Northwest Territories. Radiocarbon dates indicate that these eolian sands were deposited during the mid-Wisconsin, between 37 and 33 ka BP. These sediments were subsequently overridden by glacial ice that advanced over the area in the late Wisconsin (Dallimore et al., 1997).

In Alaska, most dune fields occur in areas that were not glaciated during the late Wisconsin and, therefore, the maximum ages of these dune fields are not constrained by the extent of glacial ice. It is hypothesized that many of the subhorizontally stratified deposits represent full-glacial eolian sand sheets; radiocarbon ages indicate that sand sheet aggradation in some lowlands occurred during the Last Glacial Maximum (ca. 25–14 ka BP), whereas many surface dunes may reflect Late Glacial and postglacial reworking (ca. 14–8.5 ka BP), and later. The surface morphology and orientations of most dune fields may, therefore, reflect reworking since the Last Glacial Maximum, rather than full-glacial paleowind directions or the age of the underlying deposits. By example, paleosols dating to ca. 24 ka BP within eolian sands in the Kobuk Valley, Alaska, may indicate regional stabilization of the dunes during the mid-Wisconsin, but with dune activity both before and after this period. There have also been repeated episodes of eolian stability and activity of at least some of these dunes in the past 8000 years.

Europe and Russia

Many detailed chronostratigraphic divisions of European dune sand, cover sand, and loess sequences have been published in the last few decades although a firm chronology of phases of eolian activity for this region is still lacking. Deposition of eolian sediments associated with the European sand belt has probably occurred over at least six Quaternary glacial periods. Eolian cover-sand sediments in The Netherlands have been dated by optically stimulated luminescence (OSL) to the last interglacial and the last two glacial stages. Three major phases of eolian deposition have been described within central and northwestern Europe. The first phase occurred during the late Weichselian glacial maximum, ca. 25–15 ka BP, with predominant fluvioeolian deposition occurring during periglacial conditions with widespread permafrost. The second, during the waning stages of glaciation, ca. 15–12 ka BP, represents the major period of sand sheet and low-dune deposition, with dominant sand-transporting winds from the northwest and a climate that was not much cooler than today. The last phase occurred between the Younger Dryas and early Holocene, ca. 11–9 ka BP. Dunes formed under west-southwesterly winds, in areas proximal to interfluvies and in river valleys, in relation to changing river channel morphology. Dune formation in the earlier phases was probably induced by a combination of factors including an abundance of unconsolidated sediment, absence of topographic obstruction, sparse vegetation cover, and a high wind-energy regime.

On the Russian Plain, radiocarbon ages of paleosols separating dune deposits from underlying alluvial sediments indicate that dune building occurred after about 15.0–12.5 ka BP, associated with the cold Late Glacial stages of the Older and Middle Dryas.

In the UK, Holocene dune activity has taken place episodically during the last 7000 years in relation to reductions in available moisture and vegetation, and disturbance by humans and livestock.

In Fennoscandia, deglaciation of the ice sheet took place between about 12.0 and 8.5 ka BP. Initial dune building probably began soon after local deglaciation. Stabilization may have occurred in several phases, beginning prior to 7 ka BP with colonization by pine trees, and continuing until about 4 ka BP with increased effective moisture and a regional rise in groundwater. Short-lived late Holocene eolian episodes have occurred due to forest fires. Increased dune activity in the last 800 years may be related to changes in climate–vegetation parameters in association with the ‘Little Ice Age’ and to the effects of trampling by reindeer.

Paleoenvironmental Significance and Future Directions

High-latitude dune fields represent informative sedimentary environments with respect to understanding Late Glacial and Holocene paleoclimates. Wind directions can be inferred from dune morphology and orientation, the dip of forest beds, and the relation of dunes to known sediment sources. These provide evidence of past localized wind regimes and regional/continental circulation patterns. Detailed chronostratigraphic sequences of eolian deposits provide information regarding the relative importance of vegetation, niveo–eolian processes, and other cold-climate (i.e., permafrost and periglacial) processes in high latitudes.

In Europe, where the greatest number of chronostratigraphic studies has been conducted, a firm chronology of the phases of dune activity is still lacking. For many other high-latitude dune fields detailed chronostratigraphic studies are still needed. For example, many stabilized dune fields in northern Canada appear to retain morphologies indicating sediment transport directions related to Late Glacial (anticyclonic) and early Holocene (westerly) wind conditions. However, no detailed chronological studies have been conducted to determine the timing of these events.

Detailed stratigraphic studies provide the means for determining the relative importance of cold-climate eolian processes in dune development in high latitudes. From previous work, it has been suggested that cold (semi-) arid conditions, rather than snow-rich climates favor niveo–eolian transport. However, despite the significance of cold-climate processes in the development of high-latitude dune fields, few analog studies are available for understanding relict eolian features and deposits. Studies are needed that document modern cold-climate eolian processes and sedimentary structures, as well as stratigraphic studies of late Wisconsin eolian deposits in permafrost environments.

In high-latitude areas, it is important to understand how the factors of transport capacity, sediment supply, and sediment availability have affected dune fields through time, and

how this compares to mid- to low-latitude dune fields. However, the inaccessibility of many high-latitude dune fields has caused our understanding of them to lag behind that of other areas. Process studies on active transverse and parabolic dunes in high-latitude areas are required in order to understand relative transport rates and sedimentary processes in these environments, and to compare to those in coastal and low-latitude areas.

In the past, dating of eolian deposits has posed a problem due to the reliance on organic materials for radiocarbon dating, which are often scarce in eolian sediments, and which typically provided ages (up to a maximum of about 27 ka BP) that only bracket the time of eolian deposition. The advent of luminescence dating, especially OSL, provides for potentially more detailed chronologies of Mid- to Late Quaternary-aged dune fields based on the eolian sediments themselves.

Coupled with more precise chronology, improved paleoenvironmental reconstructions from high-latitude dune fields are needed by integrating eolian chronostratigraphy with adjacent lake records of biostratigraphy, oxygen-isotopes, and mineralogy.

Finally, studies are needed to determine the relation between eolian sands and various source-sediment deposits. In Alaska, for example, uncertainty still exists about the relation between surficial dune deposits and underlying subhorizontally stratified deposits, variously interpreted as eolian by some workers, and alluvial or lacustrine by others. Further studies are needed here to determine the origin and age of these eolian deposits. In addition, detailed stratigraphic studies of deposits underlying and adjacent to dune deposits, and the relative amount of reworking of source materials are needed here and in other high-latitude dune fields. In this respect, mineralogical and geochemical studies that have provided insight into the origin and evolution of dune fields in mid-to-low latitudes should be applied to high-latitude dune fields.

Introduction

Large dune fields, or sand seas, are landscapes often thought to be found only in deserts beneath the great, subtropical high-pressure zones, where subsiding air suppresses rainfall. Dune fields are also quite common in mid-latitude regions, to the north and south of subtropical deserts (Figure 1). Two major characteristics distinguish many mid-latitude dune fields from the sand seas of lower latitudes. One difference is that many of those in mid-latitudes are in semiarid, rather than arid climates, and therefore are not presently active. In this article, 'active' refers to eolian sand bodies that are not covered with vegetation, and where particles are currently being transported by the wind. Evidence of active sand transport often takes the form of well-expressed sand ripples on a dune's surface. Where sand is vegetated and particles are not being transported by the wind, a sand body is 'stable.'

A second characteristic of mid-latitude dune fields is that many are situated near mountain ranges or at least areas of relatively high relief. Glaciation in high mountains reduces local bedrock to sand-sized particles, and additional reduction of rock to sand sizes takes place through colluvial and fluvial processes quickly in terrains of steep relief. Through these processes, new sediment becomes available to feed growing dune fields much more rapidly than in areas of low relief, which characterize lower latitude regions.

Because of their occurrence in semiarid climates, mid-latitude dune fields are particularly sensitive indicators of shifts in the regional moisture balance. Sand dunes move only where there is wind, sand-sized sediment, and a lack of vegetation cover. A shift to drier conditions may result in loss of vegetation cover and activation of sand by wind. A shift back to wetter conditions may stabilize dunes because of enhanced vegetation cover. The geologic record of this alternation of dry and moist climates tends to be preserved in many mid-latitude dune fields as eolian sand–paleosol sequences. In areas downslope of high sediment production, such as mountains, fresh sediment may accumulate in a dune field during periods of eolian activity, bury the preexisting landscape, and preserve former surface soils as buried soils (or paleosols). In arid, low-latitude environments of low relief, previously stabilized eolian sand may be continually reworked without addition of much new sand, and formerly stable surfaces, which would be marked by paleosols in semiarid climates, may not be preserved.

Throughout this article, we correlate eolian dune-building events, where they can be dated or where the age can be inferred, to the marine oxygen-isotope stratigraphic framework of Martinson et al. (1987). Where the abbreviation 'MIS' occurs, this refers to 'marine isotope stage,' using the numbering system and approximate ages in Martinson et al. (1987).

Dune Fields in China

Introduction

Dune fields in China form an east–west trending belt in the mid-latitude interior (latitude 35–50° N, longitude 75–125° E; Figure 2). The total desert area is 1 308 000 km², or 13.6% of China's land area (Zhu et al., 1980). These dune fields can be divided into two parts by the north–south trending Helan Mountains (Figure 2). Dune fields, west of the Helan Mountains, include the Taklimakan, Gurbantunggut, Kumtag, Qaidam, Badain Jaran, Tengger, and Ulan Buh deserts, which are situated in inland basins or adjacent to high mountains. The formation of these dune fields is a function of their inland geographic location, far from moisture sources. Climate in these deserts is controlled by the westerlies. Dune fields east of the Helan Mountains, situated in the East Asian monsoonal zone, are mainly stabilized and semistabilized at present.

Dune Types in China

The Taklimakan Desert, which is surrounded by the Tianshan and Kunlunshan mountains, is in the Tarim Basin and dominated (85%) by active sand dunes (Figure 2). The climate is extremely arid, with a mean annual precipitation of only 15–40 mm. Local residents call the Taklimakan Desert the 'dead sand sea.' Dune types are quite diverse in this desert (Figure 3), consisting mainly of complex dune chains and transverse dunes. Dunes with heights exceeding 50 m occupy 80% of the area in its interior.

The Gurbantunggut Desert is the second largest dune field in China (48 800 km²), situated in the Junggar Basin (Figure 2). The mean annual precipitation in the Gurbantunggut Desert is 70–150 mm, which is the highest among the deserts in northwestern China. Stabilized and semistabilized sand dunes occupy 97% of this desert, and linear (or longitudinal) dunes are the dominant type (Figure 4). There are also erosional landforms in the northwestern part of the desert, called 'yardangs' (Figure 5).

The Badain Jaran Desert is the third largest dune field in China (44 300 km²). The climate is extremely arid, with a mean annual precipitation of less than 50 mm. There are two remarkable properties of the landscape in this desert. First, the desert consists mainly of complex sand hills, dune chains, and pyramidal landforms called 'star' dunes, with an average height of 200–300 m. Second, as many as 144 small lakes are found in the interdune lowlands of the desert (Zhu et al., 1980). The source of these lakes is melting water of the Qilian Mountains, ~500 km to the southwest, which reaches the desert through a subsurface fault system (Chen et al., 2004). The Kumtag Desert also has complex dune chains and star-shaped pyramidal dunes. In this sand sea, heights of the dunes vary between 100 and 200 m (Figure 6).

Figure 3 Sand sea of the Taklimakan Desert. About 80% of this dune field is active at present and precipitation-to-potential-evapotranspiration (P/PE) values are generally less than 0.2 (Wang et al., 2005).

Figure 4 Semistabilized linear dunes in the Gurbantunggut Desert.

Figure 5 Deflation landforms (yardangs) in the northwestern Gurbantunggut Desert.

The Tengger Desert is the fourth largest desert in China (42700 km²). Sand dunes occupy 71% of the desert, and 93% of the dunes are active. The dominant dune type is transverse dune, with heights usually between 10 and 20 m.

The Qaidam Desert is located in the Qaidam Basin (Figure 2). Yardangs in its interior make up 67% of the desert's

Figure 6 Star-shaped pyramidal sand dunes in the Kumtag Desert.

Figure 8 Stabilized or semistabilized sand dunes are the dominant dune types in the deserts, distributed to the east of the Helan Mountains.

area (Figure 7). Sand dunes are mainly distributed in the marginal areas, dominated by transverse dunes.

Transverse dunes dominate other dune fields in China, especially those east of the Helan Mountains. Most dunes are stabilized or semistabilized (Figure 8), and vary in height between 5 and 15 m.

Origin of Chinese Dune Fields

Origins of the dune fields in China can be divided into two categories. Dune fields to the west of the Helan Mountains are situated in the inland basins near the Tianshan, Kunlunshan, and Qilianshan mountains. The mean annual precipitation varies from 20 to 150 mm. Geomorphic processes in the adjacent mountains (especially glacial grinding) have played an important role in producing the vast amounts of sand-sized materials for the formation of these dune fields. Elevations of the Tianshan, Kunlunshan, and Qilianshan mountains range mostly from ~3000 m to ~5500 m above sea level. The high elevation gives rise to extremely cold climatic conditions, thus favoring glacial grinding and frost weathering. This leads to the physical weathering of rocks in the surrounding regions, and thus the production of clastic materials (Sun, 2002a,b). The high relief and steep gradients of these mountains give rise to high potential energy of melting water. Thus, the clastic materials can be transported to the piedmont areas, forming large alluvial fans. Examination of multispectral Landsat thematic mapper (TM) imagery indicates that a series of huge alluvial fans have formed in the piedmont of the Qilian Mountains (Figure 9). The zonal distributions of the gobi (stony desert), dune fields, and loess bodies are the result of wind sorting of the piedmont fluvial materials (Sun, 2002a).

Deserts to the east of the Helan Mountains are situated in the high plains of northeastern China. Because this region lies in the East Asian monsoonal zone, the mean annual precipitation ranges from 200 to 450 mm. Most of the dunes are stabilized and semistabilized. However, due to poor land-use practices in historic time, active sand dunes also occur in these deserts, largely due to reworking of last glacial age (MIS 2) sand dunes (Sun, 2000). The provenance of the sediments in these dunes is dominantly from fluvial sediments of several large rivers.

Age of Desert Dunes

One approach for studying long-term dune field history is to examine the chronology of loess deposition, as there are few

Figure 9 Landsat thematic mapper (TM) image of alluvial fans in the piedmont of the Qilian Mountains, China. Sediments in these large alluvial fans are important sources of the dune sand and loess in China.

age estimates of the oldest dunes in China. In the northern piedmont of the Kunlun Mountains, dust derived from the Taklimakan Desert accumulates as loess sediment. Because the Taklimakan Desert lies within the rainshadow of the Tibetan Plateau, which began rising in the late Cenozoic (Gansser, 1964; Harrison et al., 1992; Molnar and Tapponnier, 1975), it is possible that dunes have existed in this basin since the latest Cenozoic.

Recent studies of eolian silt on the Chinese Loess Plateau indicate that the source areas are the gobi (stony) desert in southern Mongolia and the adjoining gobi and sandy deserts (including the Badain Jaran Desert, Tengger Desert, Ulan Buh Desert, Hobq Desert, and Mu Us Desert) in China (Figure 10). These gobi and sand deserts only serve as 'holding areas' of dust and silt, rather than the original source of loess particles. Mountain processes (especially glacial grinding) in the high elevations of Asia have played an important role in producing the vast amounts of loess-sized material for forming the Loess Plateau (Sun, 2002a). Because the basal age of the loess in the Loess Plateau is 2.58 Ma (Liu, 1985; Liu and Ding, 1993), and the loess materials are transported by the near-surface winds from the deserts listed above, these basins have been arid environments for at least 2.58 Ma.

Relations of Desert Dunes to Loess Deposits

Because Chinese loess is derived from the deserts, desert expansions and contractions, in response to Quaternary glacial-interglacial cycles, may be recorded by eolian deposits at the margins of deserts. Among the 12 deserts in China, only the Mu Us Desert is geographically proximal to the Chinese Loess Plateau. Eolian deposits on the southern margin of the Mu Us Desert are ideal for studying the response of the desert to climatic changes of the Quaternary.

The eolian deposits in the southern marginal Mu Us Desert are characterized by alternations of eolian sand, loess, and paleosols, making it a potential region for recording the ecosystem changes during the Quaternary. Eolian sand accumulated when the Mu Us Desert expanded southeasterly to the Loess Plateau during glacial maxima (Sun et al., 1999).

Paleosols developed under warm and humid conditions of interglacial periods, as a response to the enhanced summer East Asian monsoon winds. The existence of the paleosols in the desert marginal regions indicates that the dunes in the Mu Us Desert were stabilized by vegetation during interglacial maxima.

The loess beds imply intermediate climate conditions, between full glacial and full interglacial climates. The nearly unweathered character of these loess layers suggests that they were deposited under the dominant winter monsoon winds but with greatly reduced wind energy than what is necessary for sand transportation.

The most representative section of these complex eolian deposits is located at Shimao, in the southern marginal Mu Us Desert (Sun et al. (1999); see Figure 10 for location). The eolian sequences of this section consist of 40 eolian stratigraphic units, of which 13 are sands, 13 are loess, and 14 are paleosols. Based on paleomagnetic polarity studies and a comparison with the composite marine oxygen-isotope records (Shackleton and Pisias, 1985; Shackleton et al., 1990),

Figure 10 Map showing the near-surface wind directions (arrows) based on dune orientation in the studied regions. Area circled by dashed line indicates the source region of the Loess Plateau (Sun, 2002a).

the basal age of this section is about 0.63 Ma (Figure 11). The eolian deposits at Shimao and their correlation with the marine records yield two important implications.

First, during the past 0.63 Ma, there have been at least 13 times of desert expansion in the Mu Us Desert, and the desert expansion occurred not only during glacial maxima, but also during the cold substages of interglacial periods, such as those of MIS 7, 13, and 15. Intercalated eolian sand in the interglacial paleosols S2 and S5 support this conclusion (Figure 11).

A second major implication is that the stratigraphy of the section at Shimao shows that except for the Holocene paleosol (S0), all the other paleosols (S1, S2, S3, S4, and S5) are pedocomplexes, with eolian sand or loess beds intercalated within the soil complexes. The sand or loess intercalations indicate that the warm climate during each interglacial time was interrupted by cold-dry episodes.

Desert Distributions During the Holocene Optimum and the Last Glacial Maximum in China

Recent studies indicate that dust from Asia dominates the entire Pacific Ocean north of the intertropical convergence zone (Duce et al., 1991; Merrill et al., 1989). China is considered as one of the two dominant source regions for atmospheric mineral aerosols originating from Asia (Rea, 1994). The waxing and waning of the summer monsoon during the Quaternary must have had a great effect on the expansion and contraction of the deserts in northeastern China, which in turn modulated the flux of dust from Asia to the Pacific Ocean.

Former Extent of Deserts During the Last Glacial Maximum

Variation in global ice volume may have played a key role in modulating and pacing the strength of the East Asian monsoon (Ding et al., 1994). During the Last Glacial Maximum (LGM), the enlarged high-latitude ice sheets of the Northern Hemisphere greatly strengthened the Siberian High, giving rise to an enhanced cold-dry northwest winter monsoon. Under winter monsoonal winds, strong eolian erosion, transportation, and dune building characterized the arid and semiarid regions of northern China.

Since the 1980s, 44 profiles with LGM dune sands and overlying Holocene sandy loam soils have been found in northeastern China, in the monsoonal climatic zone. Thus, during the LGM, active sand dunes occurred not only in the arid inland areas of western China, but also in the semiarid to subhumid areas, east of the Helan Mountains. The existence of the buried LGM sands implies that the southern limit of the LGM desert extended south to nearly latitude 36° N, and east to longitude 125° E (Sun et al. (1998); Figure 12(a)).

Former Extent of Deserts During the Holocene Optimum

During the mid-Holocene climatic optimum, from ~9 to ~3 ka, the East Asian summer monsoon was strong. Sandy loam soils on stabilized dunes are widely distributed in desert regions, especially east of the Helan Mountains. Radiocarbon ages and optically stimulated luminescence (OSL) dating indicate that these loamy soils developed mainly between 3.0 and

Figure 11 Pedostratigraphy and the magnetic susceptibility curve of the Shima section and its correlation with the $\delta^{18}\text{O}$ records from the Pacific Ocean. The isotope curve is a composite record of V_{19-30} (0–0.34 My, [Shackleton and Pisias, 1985](#)) and ODP 677 (0.34–0.63 My, [Shackleton et al., 1990](#)). Modified from Sun JM, Ding ZL, Rokosh D, and Rutter, N (1999) 580 000 year environmental reconstruction from eolian deposits at the Mu Us Desert margin, China. *Quaternary Science Reviews* 18: 1351–1364.

9.0 ka BP, coincident with the Holocene optimum ([Li et al., 2002](#); [Zhou et al., 2001](#)). Pollen analysis of these soils indicates that the vegetation was dominated by steppe taxa, implying that sand dunes in northeastern China were stabilized during the Holocene optimum ([Sun et al., 1998](#)).

In contrast to the deserts in northeastern China, the distinctive Holocene sandy loam soil has not been found in the Taklimakan, Qaidam, and Badain Jaran deserts. Its absence implies that during the Holocene optimum, the much-enhanced summer monsoon did not penetrate into the interior of the western desert regions, and thus active dune fields existed then (and still exist today). Compared with the desert of the LGM, the extent of desert in the Holocene was greatly reduced, with the eastern limit of desert retreating from longitude 125°E (LGM time, MIS 2) to about 105°E , a distance of well over 1600 km ([Figure 12\(b\)](#)).

Dune Fields in Central Asia and South America

Central Asia

To the west of China, dune fields occupy large areas of Central Asia, in the desert basins of Kazakhstan, Uzbekistan, and Turkmenistan. The largest dune fields are situated mostly southeast of the Caspian Sea, Aral Sea, and Lake Balkhash

([Figure 13](#)). [Wilson \(1973\)](#) estimates these dune fields to encompass $\sim 380\,000\text{ km}^2$ (Karakum sand sea, southeast of the Caspian Sea), $\sim 276\,000\text{ km}^2$ (Kyzylkum sand sea, southeast of the Aral Sea), and $\sim 38\,000\text{ km}^2$ (Myunkum sand sea, southeast of Lake Balkhash). The region is semiarid to arid, and precipitation ranges from ~ 100 to 400 mm year^{-1} ([Goudie, 2002](#); [Lioubimtseva, 2002](#)).

The main dune forms in the region are longitudinal (linear) dunes, which are easily visible on Landsat imagery ([Figure 13](#)). [Goudie \(2002\)](#) reports that the linear dunes are as much as 30 m high and are separated by interdune areas floored with clay-rich sediments. [Wilson \(1973\)](#) indicates that most or all of these dunes are active at present. At the broadest scale, orientations of the dunes ([Figure 13](#)) agree fairly closely with modern, dominant wind directions ([Letollé and Mainguet, 1993](#)), but in detail, there are some differences, as pointed out by [Lioubimtseva \(2002\)](#). Southeast of the areas of linear dunes, barchans are the dominant landforms, and many of these are also active at present ([Goudie, 2002](#); [Lioubimtseva, 2002](#)).

High mountain ranges in Afghanistan, Tajikistan, and China are drained by rivers that flow westward to the basins occupied by the Caspian and Aral Seas. The Volga River, the largest river in Europe, carried sediment from the Fennoscandian ice sheet that covered northern Europe during the LGM (MIS 2). Thus, abundant sediment is delivered to the desert

Figure 12 Desert distributions in China during the Last Glacial Maximum (a) and the Holocene Optimum (b) the filled black dots indicating the sites where Holocene loam soils and the underlying sand dunes of the LGM are found (Sun et al., 1998).

basins of Central Asia at present and it is likely that even more sediment was transported there during glacial periods of the Pleistocene. Because sources of specific dune fields in the region are little studied, it is not known which rivers are most important as dune sand sources.

The paleoclimatic significance of dunes in Central Asia is difficult to assess, as there has been little study of dune stratigraphy, and numerical ages are lacking. However, as with China, some comparisons can be made with chronologies developed for loess deposits that are downwind of the dune fields. Loess deposits are extensive in the southern margins of the desert regions in Central Asia (Figure 13). Dodonov (1991) suggests that this loess is derived from a combination of glaciogenic sources in the neighboring mountains and dust sources in the

desert basins. Long-distance transport from desert basin sources is supported by the relatively fine grain size of loess particles in sections exposed in Tadjikistan (Frechen and Dodonov, 1998). Luminescence dating indicates that there was considerable loess deposition during both the early (MIS 4) and later (MIS 2) parts of the last glacial period (Frechen and Dodonov, 1998). These data suggest that winds were strong and desert basin source areas were relatively dry and minimally vegetated during the last glacial period. Nevertheless, during the early part of the last glacial period (MIS 4), the Caspian Sea was connected to the Aral Sea, whereas during the last interglacial period (MIS 5), it was of lesser extent than during the Holocene (Chepalyga, 1984). If the level of the Caspian Sea is at least a partial indicator of the overall moisture

Figure 13 Upper: map showing the distribution of eolian sand and loess in Central Asia (redrawn from data in Lioubimtseva (2002) and sources therein for sand; from Dodonov (1991) for loess). balance of the arid basins of the region, these observations suggest that the dune fields may be active primarily during interglacial, rather than glacial periods.

South America

There is a large area of stabilized dunes in the mid-latitudes of South America, primarily in the Pampas region of Argentina. The precipitation gradient in this region is steep, with present mean annual precipitation ranging from less than 500 mm (southwest) to more than 1000 mm (northeast). In parts of Argentina (particularly in La Pampa and Buenos Aires provinces), there are longitudinal (linear) dunes over 100 km long and 2–5 km wide (Figure 14). Iriondo (1999) refers to this large dune field as the Pampean Sand Sea. The largest dunes in this sand sea are arranged as extensive southwest-to-northeast arch-like forms and are presently stabilized by vegetation. Although

the longitudinal dune forms are easily recognizable on Landsat TM imagery (Figure 14), the low relief of these features makes them difficult to identify in the field (Martinez et al., 2001). A large field of parabolic dunes, most of them also stabilized and oriented in a southwest-to-northeast direction, is situated south of the longitudinal dunes (Figure 14). The parabolic dunes may have developed from reworking of preexisting sands.

Zárate and Blasi (1993) present a model for eolian deposition in Argentina that explains the origin of both dunes and loess. They report sedimentological and mineralogical data that lead them to infer that the main dune sand sources, as well as loess sources, are the Colorado and Negro River floodplains, which are situated to the southwest of the Pampean Sand Sea. The Colorado and Negro rivers drain the Andes, and thus volcanoclastic sediments from these mountains are the ultimate source of much or all of the sediment in the sand sea and loess bodies. Zárate and Blasi (1993) point out that the

Figure 14 Left: map showing the distribution of eolian sand and loess in southern South America (taken from Zárate (2003), and sources therein). Right: Landsat TM image (path 227, row 085; band 1, visible blue; image taken 17 February 1988) of linear and parabolic dunes in Buenos Aires province, Argentina.

fluvial regime supplying the particles was dependant, to a large degree, on the extent of glacial cover in the Andes. The Colorado and Negro rivers are presently underfit and have a meandering pattern. In the last glacial period, they apparently had a broad, braided pattern, and during seasonal melting periods, both rivers carried large volumes of meltwater and sediment. During periods of low flow, sediment availability was large, and provided the source of both sand to build dunes and silt for loess.

There are few data on the ages of eolian sand in Argentina. Iriondo (1999) considers the longitudinal dunes that occur in northwestern Buenos Aires province and surrounding areas to be of late Pleistocene (early last glacial, or MIS 4) age. Thermoluminescence (TL) ages reported by Kröhling (1999) indicate that the earliest part of the Pampean Sand Sea may have formed during the early part of the last glacial period (MIS 4), with reworking of this sand occurring between ~52 and ~36 cal ka BP. Kröhling (1999) also recognizes an eolian sand facies in a loess-dominated unit called the Tezanos Pinto Formation. Bracketing TL ages of ~32 and ~9 cal ka BP are reported for the loess facies of the Tezanos Pinto Formation. If these ages are correct, they imply a major period of eolian sand movement during the latter part of the last glacial period (MIS 2).

The inference of eolian sand movement occurring during major glacial periods (MIS 4 and 2) is consistent with the sediment origin model of Zárate and Blasi (1993). However, eolian sand movement may also have occurred during the Holocene. For example, Iriondo (1999) considers the parabolic dunes that are found to the southeast of the longitudinal dunes (Figure 14) to be of late Holocene age. Several workers (Iriondo, 1999; Kröhling, 1999; Zárate and Blasi, 1993) use loess and dune formation to infer a relatively dry period for the Pampas region in the late Holocene, although not as dry as during the last glacial period.

Dune Fields in North America

Introduction

Dunes occupy a considerable portion of the mid-latitude regions of North America, particularly in the Great Plains region of the central United States and the Colorado Plateau region of the southwestern United States (Figure 15). The dune fields of the Great Plains have been intensively studied since the 1980s and much is now known about their geographic extent, geomorphic expression, source sediments, chronology, and

Figure 15 Map showing the distribution of eolian sand and loess in the United States and adjacent parts of Mexico. Redrawn from Thorp and Smith (1952), Muhs and Holliday (1995), Muhs and Zárate (2001), Bettis et al. (2003) and sources therein.

paleoclimatic significance. The dunes of the Colorado Plateau have been studied less extensively, but work in progress (e.g., Redsteer and Block (2004)) promises important new information about these smaller sand seas.

Dune Forms in Mid-latitude Regions of North America

There is a wide range of dune forms in the Great Plains region of North America. The greatest variety of dune forms is found in the Nebraska Sand Hills. In this large ($\sim 50\,000\text{ km}^2$) dune field, barchanoid ridges, many 10–20 km long, are present over extensive areas (Figure 16). Most of these barchanoid ridges have smaller, superimposed parabolic dunes, indicating multiple episodes of eolian deposition. In other areas of the Nebraska Sand Hills, barchans are the main dune form (Figure 16), but again superimposed parabolic dunes indicate that the barchan forms were generated during earlier phases of dune formation. Linear (longitudinal) dunes are present over extensive areas of the Nebraska Sand Hills, many of which appear to be superimposed on older dune forms (Figure 16). The Nebraska Sand Hills subregion is semiarid and mean annual precipitation ranges from about 400 mm in the western part to about 600 mm in the eastern part. With the exception of small blowouts on dune crests, all of these dunes are presently stabilized by vegetation (Figure 17).

Dune fields farther south, in Colorado, Kansas, New Mexico, and Texas, are numerous, but are much smaller than the Nebraska Sand Hills. In eastern Colorado, for example, the

total area occupied by dunes is $\sim 25\,000\text{ km}^2$ (Madole et al., 2005). As with Nebraska, the region is semiarid and mean annual precipitation ranges from about 300 mm (west) to about 770 mm (east). The most common landforms in these dune fields are stabilized parabolic dunes, often separated by stabilized eolian sand sheets (Figure 18). In many places, compound dunes are common, with small parabolic dunes superimposed on larger, older parabolic dunes.

Still farther south, however, in the Chihuahuan Desert of southern New Mexico, western Texas, and northern Mexico, active barchanoid ridges, barchans, and parabolic dunes are found (Figure 18). Mean annual precipitation in this region is lower than on the Great Plains, and ranges from about 220 to 320 mm. Farther west, on the Colorado Plateau, many different dune forms exist in close proximity to one another. For example, in the Moenkopi Plateau of northeastern Arizona, barchan, linear, and parabolic dunes can all be found within a relatively small area (Figure 19). Mean annual precipitation on this high plateau region is lower still, and ranges from about 150 to 300 mm. As a result, while some dunes are stable, many are active. In places, for example, stabilized eolian sand sheets separate active linear dunes (Figure 19).

Dune Origins in North America

In the past, it was commonly assumed that dunes in most parts of central North America, particularly the Great Plains, were derived from local sandstone bedrock, notably the Tertiary

Figure 16 Dune landforms in the Nebraska Sand Hills, USA. All aerial photographs are from the US Geological Survey National High Altitude Aerial Photography (NHAP) program. Frames: Grant County (HAP 182-77, 25 October 1984); Thomas and Logan Counties (HAP 152-52, 31 October 1981); Arthur County (HAP 242-184, 26 September 1985).

Ogallala Formation. This formation occurs over much of the region, crops out close to the land surface, and is rich in clean sand. It is likely that many early investigators were struck by the close geographic match between the distribution of dune fields and the Ogallala Formation and inferred a genetic link. Nevertheless, much or all of the Ogallala Formation is anchored by a thick, well-cemented calcrete caprock and is not easily eroded.

Later investigators questioned the importance of bedrock as a source sediment for Great Plains dunes. Mineralogical and geochemical studies suggest that in much of the Central High Plains of Colorado and Kansas, dune sediments are derived from major rivers that head in the Rocky Mountains and flow eastward onto the Great Plains. In the Central High Plains, these fluvial sources include the South Platte River, which supplies sediment to dune fields in northeastern Colorado and southwestern Nebraska (not the Nebraska Sand Hills, however), and the Arkansas River, which supplies sediment to dunes in southeastern Colorado and western Kansas (Arbogast, 1996; Muhs et al., 1996). In the Southern High Plains of Texas and New Mexico, dune fields appear to be derived mainly from an older Pleistocene eolian sheet sand called the Blackwater Draw Formation (Muhs and Holliday, 2001), which is, in turn, probably derived from the Pecos River.

One of the greatest unanswered questions about dune fields in North America is the origin of the Nebraska Sand Hills, the largest dune field on the continent. No major rivers are situated upwind (to the northwest) of this dune field. The best available evidence, based on isotopic studies, is that it has multiple sources, most of which are sand-rich Tertiary rocks that underlie, or occur upwind of the dune field (Aleinikoff et al., 1994). Whatever their ultimate sources, dunes of the Nebraska Sand Hills are more mineralogically mature (i.e., quartz rich and depleted in feldspars) than any of their possible source sediments (Muhs, 2004; Muhs et al., 1997). One explanation for this maturity is that most feldspars have been reduced to silt-sized sediments through ballistic impacts, an idea that has support in both theory and laboratory evidence (Dutta et al., 1993). If this explanation is correct, it suggests that the Nebraska Sand Hills dune field has a long history of repeated dune activity, with little input from fresh sand sources.

Dune Ages in North America

For decades, many investigators assumed, with no numerical age control, that dunes in the Great Plains of the United States were last active during full glacial time (MIS 2). More recent studies

Western Nebraska Sand Hills, USA
 $P \sim 490 \text{ mm year}^{-1}$; $P/PE = 0.76$

Andrews dune field, western Texas, USA
 $P \sim 350 \text{ mm year}^{-1}$; $P/PE = 0.36$

confirm that the last glacial period was indeed a time of eolian sand activity over much of the region (Goble et al., 2004; Loope et al., 1995; Madole et al., 2005; Muhs et al., 1996; Swinehart and Diffendal, 1990). However, many studies also show that much eolian sand in the Great Plains region is of late Holocene age. In the Great Plains, the areal extent of late Holocene eolian sand is much greater than that of last glacial sand. For example, dunes of the Nebraska Sand Hills cover $\sim 50,000 \text{ km}^2$, yet all have only simple A/AC/C soil profiles (Entisols) that develop in a few hundred or few thousand years. This observation, along with late Holocene radiocarbon and OSL ages at numerous localities, suggests that most or all of the Nebraska Sand Hills region has been active at some time in the late Holocene. However, all parts of the dune field were not necessarily active simultaneously.

late Holocene eolian sand deposition has now been well documented in Nebraska, Colorado, Kansas, Texas, and New Mexico (Arbogast, 1996; Forman et al., 2005; Goble et al., 2004; Holliday, 2001; Madole et al., 2005; Muhs et al., 1997; Swinehart and Diffendal, 1990). Most of these studies have stratigraphic data indicating multiple periods of eolian activity in the late Holocene (Figure 20). The small number of radiocarbon and OSL ages and their large analytical uncertainties preclude testing hypotheses of regionally synchronous activity. However, these observations show that eolian sand in this region has been active under modern climatic regimes. Explorers in the nineteenth century observed active dune sand in many parts of the Great Plains where it is now stable (Muhs and Holliday, 1995).

Paleoclimatic Significance of Dunes in North America

One of the most important paleoclimatic inferences made from stabilized, mid-latitude dune fields is that periods of dune activity indicate drier-than-present climate. Many factors influence the degree of dune activity, including wind strength, sediment availability, and degree of surface disturbance by animals or human activity. Nevertheless, several studies show that in many regions, including southern Africa (Lancaster, 1988; Thomas et al., 2005), China (Wang et al., 2005), and North America (Muhs and Holliday, 1995; Wolfe, 1997), the degree of dune activity is influenced to a great extent by the amount of plant cover, which in turn is influenced significantly by moisture balance. Moisture balance can conveniently be

calculated, at least to a first approximation, by the ratio of precipitation (P) to potential evapotranspiration (PE). Values less than 1.0 indicate a net moisture deficit and are typical of regions with semiarid, arid, or hyperarid climates. In areas where P/PE is greater than about 0.35–0.40, dunes are stabilized by vegetation. When P/PE is less than about 0.35–0.40, dunes are at least partially active, and as this ratio diminishes, dune activity increases (Figure 17). In desert regions of the southwestern United States and northwestern Mexico, P/PE is less than about 0.25. Thus, dunes in the Chihuahuan Desert, Algodones, and Gran Desierto dune fields (Figure 15) are quite active (Figure 18). In the Taklimakan Desert of China, eolian sand is active over most of the dune field (Figure 3) and P/PE

values for stations in and around this sand sea are less than 0.2 (Wang et al., 2005). With these observations in mind, it can be inferred that in areas now characterized by stable dunes, past periods, represented by eolian sand, were more arid than present. In contrast, periods represented by paleosols were times that may have had a moisture balance similar to the present.

One of the remarkable observations of many North American Great Plains dune field records is the presence of multiple paleosols, all dating to the Holocene, intercalated within eolian sand (Figure 20). The evidence for multiple periods of dune activity and stability in the past few thousand years indicates that Great Plains eolian sand is quite sensitive to small changes in the overall moisture balance and degree of vegetation cover. As in the Mu Us Desert in China, the Great Plains region of North America is highly sensitive to fluctuations in the strength of a monsoonal moisture source. In central North America, the main monsoonal flow of moist air is from the Gulf of Mexico in summer. When this flow is diminished,

summer precipitation is lower and vegetation cover is reduced. Dry periods in the Great Plains are characterized not only by decreased summer monsoonal flow from the Gulf of Mexico, but also by an increase in zonal, or westerly flow of Pacific air (typically a winter pattern). Pacific air is usually dry by the time it reaches the Great Plains. Moisture in Pacific air masses is lost on north–south trending mountain ranges between the Pacific Ocean and the Great Plains (Figure 15). Reactivation of stabilized dune sand or mobilization of new sand by wind is enhanced under conditions of reduced vegetation cover during periods of decreased monsoonal flow and increased zonal flow.

Another important application of dunes to paleoclimate studies in mid-latitude North America is wind direction inferred from dune orientation. Most of the late Holocene dunes in the midcontinent of North America are parabolic forms, which are excellent paleowind indicators. Parabolic dunes have arms that point upwind, with noses that face downwind, as seen when they are active in areas such as

Figure 21 Map showing the distribution of eolian sand in the Great Plains, United States, direction of modern, sand-moving winds, and late Holocene paleowinds based on dune orientations. Modified from Muhs DR and Zárate M (2001) Late Quaternary eolian records of the Americas and their paleoclimatic significance. In: Markgraf V (ed.) *Interhemispheric Climate Linkages*, pp. 183–216. San Diego: Academic Press. Also shown (green circles) are localities where there are late Holocene radiocarbon or OSL ages for eolian sand. From Swinehart and Diffendal (1990), Arbogast (1996), Muhs et al. (1997), Holliday (2001), Goble et al. (2004), Forman et al. (2005), Madole et al. (2005). Modern sand-moving winds constructed using methods of Fryberger and Dean (1979).

White Sands, New Mexico (Figure 18). On the Great Plains of North America, orientations of many late Holocene dunes indicate northwesterly winds in Nebraska, and northern and central Colorado (Figure 18), similar to modern, sand-moving wind regimes of fall, winter, and spring (Figure 21). Such orientations are consistent with the scenario of increased zonal or westerly flow discussed above. Late Holocene dunes in southeastern Colorado and Kansas have orientations that indicate southwesterly paleowinds, again similar to present. However, in eastern New Mexico and western Texas, dunes have orientations that indicate northwesterly winds, whereas modern dune-forming winds are dominantly from the southwest. One explanation is that during the periods of late Holocene dune formation, there was less of an influence from southwestern (Gulf of California), monsoonal airflow, and a greater influence from zonal (westerly) circulation.

Conclusion

Large dune fields, or sand seas, are widespread in the interiors of continental mid-latitudes. Most of them are found in China, Central Asia, Argentina, and the United States. Mid-latitude dune fields in the United States are generally smaller than those of low latitudes, but those in China, Central Asia, and Argentina are quite large. Where climates are arid, such as in western China and Central Asia, active dunes dominate these sand seas. Other dune fields, in the semiarid climates of eastern China, Argentina, and the United States, have mostly stabilized dunes. Mid-latitude dune fields are often near mountains, which supply much of the sediment to the sand seas on a regular basis, particularly during glacial periods. Many different kinds of eolian landforms are found in mid-latitude sand seas, including transverse dunes, longitudinal (linear) dunes, star dunes, parabolic dunes, and eolian sand sheets. Where dune fields of mid-latitudes occur in semiarid climates, they are particularly sensitive indicators of shifts in climate. In China, records of dune field expansion and contraction extend back hundreds of thousands of years.

This article is reproduced from the previous edition, volume 1, pp. 626–642, © 2007, Elsevier B.V.

Low-latitude sand seas (also called ergs) are extensive areas of sand dunes located in the tropical and subtropical deserts of the world ([Figure 1](#)), where they occupy as much as one-third of the area classified as arid. Major low-latitude sand seas occur in the Sahara and Arabian Deserts, the Thar Desert of India, the interior of Australia, and in southern Africa (Namib and Kalahari Deserts). Large sand seas are absent in the Americas, where areas of dunes cover less than 1% of the area classified as arid. Important studies and surveys of low-latitude sand seas include those by [Wilson \(1973\)](#) and [McKee \(1979\)](#). [Lancaster \(1999\)](#) provided a review of modern paradigms of sand sea geomorphology. Important summaries of chronologic data include [Munyikwa \(2005\)](#) for Southern Hemisphere sand seas, [Glennie and Singhvi \(2002\)](#) for Arabia, and [Swezey \(2001\)](#) for the Sahara.

Sand seas contain large volumes of sand (tens to hundreds of cubic kilometers) and have accumulated episodically during the Quaternary. Their construction has therefore been determined by climatic, tectonic, and sea-level changes that have affected sand supply, availability, and mobility, as well as the preservation of deposits and landforms from prior episodes of eolian construction. As significant sedimentary deposits in low-latitude desert regions, sand seas also provide an archive of the effects of climate change on these areas.

Sand seas and dune fields typically form part of well-defined regional- and local-scale sediment transport systems in which sand is moved by wind from source areas (e.g., distal fluvial deposits and sandy beaches) via transport pathways to depositional sinks. Sand seas accumulate downwind of source zones wherever sand transport rates decrease as a result of regional and/or local changes in wind speed and directional variability so that the influx of sand exceeds outflux. A conceptual model for the response of low-latitude (and other) sand seas to changes in external forcing factors was provided by [Kocurek and Lancaster \(1999\)](#). In this model, episodes of sand sea construction are viewed as the product of changes in the supply, availability, and mobility of sand-sized sediment. Sediment supply is the deposition of sediment that is a source for the eolian system either contemporaneously or at some later time. Availability of sediment for transport by the wind (the probability of entrainment of sand for transport) is strongly influenced by variations in vegetation cover and soil moisture. In addition, changes in sea level and regional hydrology may make the sediment stored in shallow marine or lacustrine environments available for transport. The mobility of sediment is determined by the transport capacity of the wind (the potential rate of sediment transport).

Evidence for Paleoenvironments in Low-Latitude Sand Seas

Sand seas provide paleoenvironmental information from three main sources: (a) dune systems, especially those stabilized by

vegetation; (b) interdune deposits; and (c) penetration of extra-dune fluvial deposits into the margins of the sand sea. The quality of paleoclimatic data provided by sand seas is frequently much better than that obtained from adjacent rocky desert regions, because sand dune areas tend to accentuate the effects of both dry and wet phases ([Rognon, 1982](#)). In periods of increased rainfall, the high infiltration capacity and porosity of dune sands favor the growth and persistence of vegetation, which may lead to the partial or complete stabilization of the dunes and formation of soils on dune sands ([Figure 2](#)). If the periods of increased rainfall are of sufficient magnitude and duration, then water tables may rise, leading to the formation of pond and marsh deposits in interdune areas. In contrast, periods of aridity will give rise to a very unfavorable biotic environment in which vegetation cover is reduced as a result of low precipitation and active sand movement. In addition, dune systems provide some of the best indicators of past wind regimes and atmospheric circulation patterns (e.g., [Lancaster et al., 2002](#)).

Many sand seas contain a variety of dune types or dunes on different trends, often forming complex patterns. Satellite image analysis, combined with studies of dune geomorphology and sedimentology, can be used to analyze the dune patterns, identify genetically distinct generations of dunes, and interpret the conditions in which they formed. The understanding of the history of sand seas and dunes has been revolutionized in recent years by the application of luminescence techniques to directly date periods of dune formation and/or reactivation ([Stokes, 1997](#)). In addition, large dunes, especially those of linear form, appear to be composite features, reflecting many generations of dune construction and stability. Recent application of ground-penetrating radar techniques has enabled identification of major sedimentary units and bounding surfaces prior to luminescence dating of these units ([Bristow et al., 2005](#)).

Sand seas may also contain evidence of periods of climates wetter than present, in which dunes were stabilized by vegetation and soil formation and marshes and shallow lakes formed in interdune areas. Many of these deposits contain fossil biota and/or archaeological materials that can be used to reconstruct past hydrology and vegetation communities and provide ages for periods of wetter climates ([Gasse, 2002](#); [Teller et al., 1990](#)). Stratigraphic relations between such deposits and those of dunes have traditionally been used as a major source of chronologic information for sand seas in the Sahara ([Swezey, 2001](#)) and elsewhere.

In many areas, the evidence for environmental change from the sand seas is corroborated by records of dust flux (indicating arid, windy conditions) from marine sediment cores in adjacent ocean and shelf areas, which frequently provide a more continuous and better dated record than that of the sand seas ([deMenocal et al., 2000](#); [Stuut and Lamy, 2004](#)).

Regional Summaries

Sahara Desert

The Sahara Desert contains a significant proportion of the global inventory of wind-blown sand as well as some of the world's largest sand seas, which cover approximately 28% of this desert. There is a large amount of paleoenvironmental information on Saharan sand seas, much of it based on analyses of dated interdune lacustrine deposits and their stratigraphic relations to dune deposits (Gasse and Van Campo, 1994; Swezey, 2001). However, there are few examples of episodes of eolian deposition that have been directly dated by luminescence techniques.

The major sand accumulations are situated on each side of the central Saharan uplands, where there is very little sand (Figure 3). In the Sahara, sand is moved long distances between apparent source areas and depositional sinks as well as from one sand sea to another. In many instances, the source of sand is not clear or not known. The high degree of mineralogical maturity of sand from Libyan sand seas (Muhs, 2004) suggests long-distance transport, repeated periods of transport and reworking over short distances, or a source in the mineralogically mature Nubian Sandstone that crops out extensively in the eastern Sahara.

The sand transport pathways, clearly visible on satellite images (Breed et al., 1979; Mainguet, 1984), reflect the dominance of the trade wind circulation that tends to move sand from the sand-poor eastern and central parts of the desert toward thick sand accumulations in the Sahel and from the piedmont of the Atlas Mountains and the Mediterranean coast

to the northern and western sand seas (Mainguet and Chemin, 1983; Wilson, 1971). The location of the major Saharan sand seas is controlled both by patterns of winds and by topographic obstacles. The Grand Erg Occidental and the Ubari and Murzuq sand seas of Libya have accumulated against the northern slopes of the central Saharan uplands (Fryberger and Ahlbrandt, 1979). Sand seas in the Akchar of Mauritania and the Fachi-Bilma region of Tchad lie where winds converge in the lee of escarpments or mountain masses. The thick sand accumulations of the southern Sahara and Sahel have developed because wind energy is reduced on the margins of the trade wind circulation. Many northern Saharan sand seas (e.g., the Grand Erg Occidental and Oriental) occur in areas of complex or multidirectional wind regimes influenced by trade wind and mid-latitude cyclonic circulations as well as local topographically induced winds (Wilson, 1971).

Dune patterns in Saharan sand seas are summarized in Table 1. The northern Saharan sand seas are characterized by complex crescentic and star dunes developed in a multidirectional wind regime that results from the effects of both trade wind and mid-latitude circulations. By contrast, sand seas in the western and southern Sahara are mainly composed of linear dunes, with small areas of crescentic dunes. The dominance of linear dunes in these areas reflects the persistence of trade wind circulations. Eolian accumulations in the eastern Sahara are dominated by extensive sand sheets and areas of gently undulating dunes with a chevron pattern. The formation of extensive sand sheets is attributed to the abundance of coarse sand derived from the Mesozoic Nubian Sandstone that underlies much of the area (Stokes et al., 1998).

Figure 2 A conceptual model for the response of dune areas to climate change. Note the contrasts between arid and more humid conditions. Reproduced from Rognon P (1982) Pluvial and arid phases in the Sahara: The role of non climatic factors. *Palaeoecology of Africa* 12: 45–62.

In addition to the largely active sand seas of the Sahara, satellite images show the existence of large areas of vegetation-stabilized dunes on the southern margins of the desert, extending south into Sahel and beyond (Figure 4). Extensive systems of mainly linear dunes occur in areas that today receive as much as 1000 mm of rainfall per year. These dunes, which are today extensively degraded and covered by savanna vegetation, were first recognized on aerial photographs of northern Nigeria and southern Mauritania and subsequently mapped throughout the Sahel (Grove and Warren, 1968). A regionally extensive paleosol is present within these dunes (Mauz and Felix-Henningsen, 2005). This paleosol indicates a past period of stability, similar to the present one. In areas to the north, this paleosol underlies late Holocene to modern dunes, many of them of crescentic form.

The age of the stabilized dunes in the Sahel has been hypothesized to be last glacial, spanning the period 20–13 ka (Ogolian period in the western Sahara), mostly by stratigraphic relations to overlying lacustrine deposits dated by radiocarbon methods (Swezey, 2001). Direct age estimates for these dunes using optically stimulated luminescence (OSL) are limited to those in northeastern Nigeria (Stokes and Horrocks, 1998), where maximum rates of construction occurred 18–13 ka, and in the Sahel of Mali, with an age of 12.7 ka.

In western Mauritania, where dunes are today largely active, combined geomorphic and OSL dating studies (Lancaster et al., 2002) show that three main generations of linear dunes were formed during the periods 25–15 ka (centered around the Last Glacial Maximum – LGM), 13–10 ka (spanning the Younger Dryas event) and after 5 ka. The wind

Figure 3 Location of Saharan sand seas and vectors of sand transport. Sand seas are numbered as follows: 1. Grand Erg Occidental, 2. Grand Erg Oriental, 3. Ubari, 4. Murzuq, 5. Calanscio, 6. Great Sand Sea, 7. Selima, 8. Fachi-Bilma and Tenéré, 9. Majabat al Koubra, 10. Aouker, 11. Akchar, 12. Iguidi, and 13. Chech. Reproduced from Mainguet M and Chemin MC (1983) Sand seas of the Sahara and Sahel: An explanation of their thickness and sand dune type by the sand budget principle. In: Brookfield ME and Ahlbrandt TS (eds.) *Eolian Sediments and Processes. Developments in Sedimentology*, pp. 353–364. Amsterdam: Elsevier; Mainguet M (1984) Space observations of Saharan aeolian dynamics. In: El Baz F (ed.) *Deserts and Arid Lands*, pp. 59–77. The Hague: Nyhoff.

regimes that occurred during each of these periods were significantly different, leading to the formation of dunes on three distinct superimposed trends – northeast, north-northeast, and north (Figure 5). The period from approximately 9 to 5 ka was characterized by formation of shallow lakes in interdune areas and formation of soils on the dunes (Kocurek et al., 1991).

Sedimentary and OSL dating studies of the Selima sand sheet in the eastern Sahara (Stokes et al., 1998) indicate two major episodes of accumulation at 20–15 and 4–3 ka, separated by an early to mid-Holocene pluvial period during which a regionally extensive paleosol formed and local wadi and lacustrine deposits were laid down.

Directly dated information on the response of sand seas on the northern margins of the Sahara to Quaternary climate change is sparse, but a detailed luminescence-dated record

from the Chott Rharsa area of southern Tunisia suggests formation of gypsum-rich dunes and low lake levels 12–10, approximately 7.5, and 6.2–5.6 ka (Swezey et al., 1999). In summary, OSL ages, together with stratigraphic relations between eolian sands and ^{14}C -dated lacustrine deposits, indicate widespread eolian activity and dune formation in the Sahara from 25 to 11 ka, with extensive stabilization of dunes in the southern and western Sahara in the period 11–5 ka (the African Humid Period, deMenocal et al., 2000). The African Humid Period was apparently not uniformly humid throughout this region. Gasse and Van Campo (1994) summarized evidence for a widespread period of aridity 8.8–7.8 ka, with some areas experiencing dry conditions at 6.8 ka. The period after 5 ka appears to have been arid, with renewed formation of dunes and/or reworking of existing deposits.

Table 1 Distribution of dunes in selected sand seas

	Percentage of dune area covered								
	Sahara				Kalahari	Namib	Arabia	Thar	Australia
	South	North	Northeast	West					
Linear dunes	24.08	22.84	17.00	35.50	85.55	32.55	49.81	13.96	95.00
Crescentic dunes	28.37	33.34	14.50	19.20		11.80	14.91	25.61	
Star dunes		7.92	23.90			9.92	5.34		
Sand sheets and streaks	47.54	35.92	39.20	45.30	13.56	45.44	23.24	31.75	5.00
Parabolic dunes					0.60			28.68	
Undifferentiated			4.50				6.71		

Data from Fryberger and Goudie (1981).

Kalahari Desert

Extensive systems of dunes, mostly of linear form and stabilized by vegetation, occur in the northern and southwestern Kalahari (Figure 6). The dunes can be divided into three groups (Thomas and Shaw, 1991). The eastern and northern groups of dunes are variably degraded and covered by savanna vegetation. They are also truncated by some of the major river systems in the area as well as by the Okavango Delta. The southern group of dunes occurs in the southwestern Kalahari in a 100–200-km-wide belt that extends from the highlands of Namibia to the Orange River. Dunes consist of 2–15-m-high simple and compound linear ridges. Vegetation cover on the dunes consists of grasses with scattered trees and shrubs, but the dune crests are commonly unvegetated and active sand movement takes place seasonally.

Until the recent application of luminescence dating techniques, the age(s) of the Kalahari dune systems was unknown or inferred only by relations to dated lacustrine and fluvial

deposits. Luminescence dating and stratigraphic investigations show that the last major period of linear dune development in the southern dune system occurred between 16 and 10 ka and probably involved reworking of sediment deposited in a previous period of dune building from 30 to 23 ka that may represent the initial deposition of sand in this region (Stokes et al., 1997b). Holocene dune activity in the region was localized in extent and occurred at 6 and –2 to 1 ka (Thomas et al., 1997), although the final stabilization of linear dunes may have occurred as recently as 8–9 ka in drier western areas of the region.

Parallel studies of dune chronology in the northern and eastern dunes indicate that multiple periods of dune building, each spanning several thousand years, occurred during the late Pleistocene and Holocene (Stokes et al., 1997c). OSL ages for these periods are 115–95, 46–41, and 26–20 ka. Short-lived periods of aridity were separated by much longer (40–20 ka) periods of humid conditions. Late Glacial and Holocene eolian

Figure 5 Effects of climate change on Mauritania dune systems. (a) Major dune trends. Reproduced from Lancaster N, et al. (2002) late Pleistocene and Holocene dune activity and wind regimes in the western Sahara of Mauritania. *Geology* 30(11): 991–994. (b) Landsat image of the Azefal, showing three dune generations. (c) Schematic cross-section of dunes in this area, showing superimposition of dune genetic units. Reproduced from Kocurek G, Havholm KG, Deynoux M, and Blakey RC (1991) Amalgamated accumulations resulting from climatic and eustatic changes, Akchar Erg, Mauritania. *Sedimentology* 38(4): 751–772.

activity was restricted to reworking of the crestal areas of the linear dunes in the area of Hwange National Park in the period –16 to 10 ka and to western Zambia, where linear dune construction from local sediment sources occurred 32–27, 16–13, and 10–8 ka (O'Connor and Thomas, 1999). Dune construction is indicated for the periods 48–41, 36–29, and 23–21 ka in the linear dunes of northern Namibia (Thomas and Shaw, 2002).

Namib Desert

The main Namib sand sea occupies an area of approximately 34 000 km² between Luderitz and the Kuiseb River and the coast and the base of the Great Escarpment of Namibia (Figure 6). The sand sea is characterized by crescentic dunes near the coast, with north–south trending linear dunes inland and clusters of star dunes and reticulate or network linear dunes inland (Lancaster, 1989). Despite the existence of multiple generations of dunes in this sand sea, there is little information on their age. OSL dating studies on the northern margin of the sand sea give ages for the base of one linear

dune of between 0.34 ± 0.02 and 1.57 ± 0.07 ka, indicating a dune migration rate of approximately 0.12 My^{-1} during the past 1600 years (Bristow et al., 2005). Studies of interdune lacustrine deposits (Teller et al., 1990) indicate widespread conditions favorable for shallow lakes and ponds in the periods 12–8, 24–20, and 32–26 ka, although the state of the adjoining dunes is not clear.

Additional small dune fields dominated by crescentic dunes occur in the northern Namib in the area known as the Skeleton Coast. A Holocene age for the Skeleton Coast dune field is suggested by the small sand thickness represented by the dunes and their simple patterns. Aerial photographs and satellite images indicate that the Engo–Kunene and Baia dos Tigres–Curoca sand seas are characterized by a similar assemblage of dunes, but increased reddening inland suggests a greater chronologic complexity for this area.

Australian Deserts

Dunes cover as much as 40% of the Australian landscape, with the majority in the Simpson–Strzelecki and Tirarai Deserts

Figure 6 Dune systems in southern Africa, with Landsat images of examples of linear dunes in different areas. Dunes after Thomas DSG and Shaw PA (1991) *The Kalahari Environment*. Cambridge: Cambridge University Press.

(Figure 7). Continent-wide patterns of dunes in Australian sand seas and dune fields have been documented (Wasson et al., 1988). Although linear dunes dominate, short, narrow-crested varieties appear to occur where sand transport is limited by vegetation cover; broad-crested linear dunes are found in the northern parts of the dune system, and narrow-crested varieties are found in the south. Network dunes occur in small basins in the central parts of the continent where the directional variability of the wind regime is high. Mapping of patterns of sediment thickness, together with sedimentological and mineralogical evidence, shows that most sand in the Australian deserts has only moved short distances from its source, although the dune pattern suggests an organized continent-wide sediment transport system (Pell et al., 2000; Wasson, 1988).

A variety of luminescence dating studies indicate discontinuous dune construction in the Simpson–Strzelecki dune field

between 35 and 9 ka, with older periods of activity between 65 and 45 ka and at approximately 78 ka (Munyikwa, 2005). Localized periods of eolian activity also occurred during the Holocene. In all instances, periods of eolian construction were coeval with periods of low lake levels in the region (Wasson, 1983).

Arabian Deserts

The Arabian Peninsula is dominated by extensive dune systems, including the world's largest sand sea, the Rub al Khali, the Nafud, and Ad Dahna, all influenced by the northwesterly Shamal wind system (Figure 8). The Wahiba sand sea of Oman comprises a separate system on the coast, influenced by the southwest monsoon circulation.

Figure 7 Dune systems in Australia. Landsat images of examples of linear dunes in the Great Sandy and Simpson–Strzelecki deserts. Dune trends and extent after Jennings (1968).

A characteristic feature of eolian sedimentation in the Wahiba sand sea and the United Arab Emirates (UAE) is the existence of thick sequences of carbonate-cemented sand (eolianite) that underlie the more quartz-rich dunes. Limited stratigraphic evidence and clustering of OSL ages on the eolianites in the UAE indicate that they formed during the periods 164–129, 113–99, 64–34, and 22–18 ka from bioclastic sediments deflated from the shelf areas of the Arabian Sea during periods of low sea levels (Glennie and Singhvi, 2002). Wind directions during these periods of dune construction were from the northwest/north-northwest. In the Wahiba, periods of accumulation of eolianites occurred 160–140, 34–24, 16–13, and approximately 9–8 ka (Preusser et al., 2005).

The southern parts of the Rub al Khali are dominated by large complex linear dunes, whereas its northern parts exhibit a complex pattern of dune construction, reactivation, and stabilization in response to changes in sea level and climate. In the UAE and adjacent areas, the largest and most widespread dunes are west-to-east-oriented complex linear dunes, with superimposed crescentic dunes in the north and east and star dune peaks in the southeast of the UAE. These dunes are composed mainly of quartz sand and are being reworked in northern areas by northwest winds into crescentic dunes and obliquely oriented small linear dunes that are superimposed on the linear dunes. The linear dunes appear to have been formed (or reformed) during the LGM, as indicated by OSL ages of 42–31, 18–15, and 12–9 ka in the UAE.

Figure 8 Sand seas and dune fields of the Arabian Peninsula. Insets: (a) aster image of linear dunes in the Rub' al Khali, (b) compound crescentic dunes in the Liwa area, and (c) linear dunes in the Wahiba Sand Sea. Dune extent and schematic dune trends after Glennie KW and Singhvi AK (2002) Event stratigraphy, paleoenvironment and chronology of SE Arabian deserts. *Quaternary Science Reviews* 21: 853–869.

In the Liwa area, large, quartz-rich compound crescentic dunes overlie inland sabkhas. Stratigraphic and geomorphic evidence, together with OSL dating of eolian sands, indicates deposition of eolian sand in the period 130–75 ka (Stokes and Bray, 2005) and after 7.8 ka, peaking at 2.8 ka, but no record from the LGM. The water table in this area was several meters higher than present during the period 41–29 ka (Wood and Imes, 1995).

In the Wahiba sand sea of Oman, a large inland part of the sand sea is characterized by 50–100-m-high south–north trending complex linear dunes. In places, the crestal areas of these dunes are overlain by crescentic and network dunes. To the south of the large linear ridges are smaller (10–30 m high) vegetated linear dunes with 300–500-m spacing. There are three groups of simple and compound crescentic and network dunes near the coast. These groups of dunes overlie cemented carbonate sands (eolianites), which crop out on the southern and western edges of the sand sea. An extensive program of drilling and luminescence dating of dune sands and eolianites in the central parts of the sand sea indicates that periods of eolian accumulation occurred 24–11, 78–65, 120–100, and 160–140 ka (Preusser et al., 2002; Radies et al., 2004).

The main south–north-oriented linear dunes were formed at approximately 20 ka. The coastal part of the Wahiba exhibits a different timing of eolian accumulation, with dune building at 34–24, 16–13, and approximately 9–8 ka (Preusser et al., 2005). In contrast to the main dune area, there was little dune activity at the LGM and during the Younger Dryas. The area experienced wetter conditions with high groundwater levels during the early Holocene.

Thar Desert

The Thar Desert in northwestern India (Figure 9) is dominated by compound parabolic dunes, with smaller areas of linear, crescentic, reticulate, or network dunes and sand sheets (Kar, 1993). The dunes are underlain in part by carbonate-cemented eolianites, which range in age from 21 to 210 ka. Dune trends indicate their formation by winds associated with the southwest monsoon. Many of the dunes are partially or completely stabilized by vegetation, and the limit of stabilized dunes extends into areas where the mean annual rainfall exceeds 500 mm.

Figure 9 Dunes in the Thar Desert. Inset: aster image of parabolic dunes. Reproduced from Singhvi AK and Kar A (2004) The aeolian sedimentation record of the Thar Desert. *Proceedings of the Indian Academy of Sciences (Earth Sciences)* 113(3): 371–401.

The Thar Desert was the site of some of the first luminescence dating studies on eolian deposits (Singhvi et al., 1982), and subsequent studies have resulted in the development of a detailed chronology of dune-building episodes in the region (Singhvi and Kar, 2004). Eolian deposition in the area dates to 150 ka or older; major periods of construction occurred 115–100, ~75, ~55, and between 30 and 25 ka.

The available data suggest that despite an arid climate and an abundant sediment supply from the exposed shelf of the

Arabian Sea, late Pleistocene dune building in the Thar Desert did not occur coeval with the LGM but instead took place in a narrow window of time (14–10 ka) as the southwest monsoon was reestablished at the Pleistocene–Holocene transition. Major eolian activity occurred in the Holocene, but with important spatial variability. Dune building ceased in the southern Thar Desert in the early Holocene (10 ka) but continued until 5 ka in the north. In the core arid region of western Rajasthan, dune activity continued after 2 ka to 0.7–0.8 ka.

Figure 10 Distribution of dune fields in the Mojave and Sonoran deserts, with Landsat images of selected dune fields. Gran Desierto image shows star dunes in linear chains (26–12 ka) and crescentic dunes formed ~12 ka.

North American Deserts

Dune fields are limited in extent in the deserts of the southwestern United States and adjacent areas of Mexico (Figure 10). Sand deposits are composed of sand sheets, small dune fields, and sand ramps (amalgamated accumulations of eolian sand, and alluvial and colluvial deposits on the slopes of desert mountains).

Mojave Desert

Eolian sediments and landforms in the Mojave Desert of southern California and adjacent areas of Nevada and Arizona are concentrated along well-defined eolian sediment transport corridors that are characterized by areas of active and inactive

dunes and sand sheets, together with sand ramps. Geochemical and mineralogical studies indicate several major (e.g., the Mojave River and Colorado River) and many local sources of sediment, but there is a general west-to-east transport of sand.

The history of Late Quaternary eolian activity along the major sand transport corridors has been documented using thermoluminescence and infrared-stimulated luminescence (IRSL) dating of dunes and eolian deposits in sand ramps (Clarke and Rendell, 1998; Lancaster and Tchakerian, 2003). These indicate periods of eolian activity 30–20 and 15 or 20–7 ka. Mid- and late Holocene eolian deposits occur in the Kelso Dunes. Interstratified paleosols in many sand ramps (e.g., near Kelso Dunes and Rice Valley dune field) suggest one major and a number of minor periods of regional-scale

eolian stability 20–15, 14, and 4 ka. Comparison of the record of periods of eolian construction and stability in the Kelso Dunes system with the lacustrine record from Lake Mojave suggests that periods of eolian stability generally coincide with the highest lake levels, whereas periods of eolian construction are linked to periods of fluctuating or desiccating lakes but also overlap with periods of high lake levels. These observations indicate a strong influence of sediment supply on eolian processes in this region.

Multiple, short-duration episodes of late Holocene eolian accumulation are recorded close to modern sand source areas. IRSL ages for sediments in the Kelso Dunes (including the Cronese basins) cluster around 0.20–0.14, 0.5–0.4, 0.85–0.7, 1.7–1.4, 3–2, 4.2–3.5, and 6.7–5.4 ka. Episodes of eolian deposition correlate well with the record of major floods in the Mojave River system and likely reflect the effect of enhanced sediment supply from the Mojave River (Muhs et al., 2003).

Colorado and Sonoran Deserts

There are three main areas of eolian deposits in the Colorado and lower Sonoran Deserts: the Coachella Valley, the Algodones Dunes, and the Gran Desierto sand sea of northern Mexico (Lancaster, 1995).

The largest dune field in the Sonoran Desert lies in the Gran Desierto of northern Mexico, which has a spatially complex pattern of multiple generations of linear, crescentic, and star dunes, as well as extensive sand sheets (Figure 10), sourced mainly from Colorado River sediments. Recent OSL dating and geomorphic studies show that elements of the complex pattern represent short-lived eolian constructional events since ~25 ka. The simple dune patterns consist of late Pleistocene relict linear dunes formed between 25 and 12 ka, degraded crescentic dunes formed at ~12 ka, eastern crescentic dunes emplaced at ~7 ka, early Holocene western crescentic dunes, and star dunes formed during the past 3 ka (Beveridge, 2004). In the Algodones, Stokes

et al. (1997a) identified periods of eolian activity >30 ka, ~3.1 and <0.4 ka.

South America

Low-latitude dune fields occur in two settings in South America: (a) the largely active dunes of the Atacama Desert on the west coast and (b) the vegetation-stabilized relict dune fields of the Rio Negro and Sao Francisco areas of Brazil and the northern Pampa in Argentina. Chronologic data for the relict dune fields are summarized by Munyikwa (2005) and suggest eolian activity prior to 69 ka and at 63, 33, 28–27, 23–22, and 17.2–8 ka, with limited Holocene activity.

Conclusion

The available chronologic information shows that most sand seas have experienced episodic accumulation during the past 120 ka, with long periods of stability or nondeposition separated by relatively brief periods in which dune construction occurred (Figure 11). Luminescence dating indicates widespread dune activity in low-latitude deserts during the periods 120–100, 35–10, and since 5 ka. However, subsequent periods of eolian activity have reworked older deposits so that the preserved record in many areas is quite short.

The episodic nature of sand sea construction in low-latitude deserts is a direct consequence of the interplay between sand supply, availability, and mobility (Figure 12). Thus, sediment supplied to source areas during periods of increased fluvial activity is mobilized when it becomes available for transport in subsequent drier episodes, as occurred in the Simpson–Strzelecki Deserts in the late Pleistocene, the Mojave Desert in the early Holocene, and throughout the Sahara in the late Holocene. In other areas (e.g., UAE and Wahiba), sediment

supplied to shelf zones by biogenic activity became available for transport to dunes as sea level fell. In the case of the Wahiba sand sea and the Thar Desert, this sediment was only mobilized as the strength of the southwest monsoon increased following the LGM.

Sarnthein (1978) summarized the then available evidence for Late Quaternary eolian activity in low-latitude arid regions. He concluded that dune fields were much more extensive at the LGM (~20 ka). The recent infusion of chronologic information from luminescence dating studies broadly confirms Sarnthein's hypothesis but suggests that the temporal and spatial patterns of dune construction are more complex than those proposed by Sarnthein (Figure 11). For example, there was no dune construction in the northern Kalahari and Thar Deserts at this time.

Many areas of dunes, especially those composed of linear dunes, were formed or reformed during the LGM. Arid conditions and eolian activity increased in extent and/or intensity during this period, as corroborated by the record of dust flux in adjacent ocean cores. This was apparently the result of increased intensity and persistence of the trade wind circulation in the Sahara and elsewhere giving rise to increased sediment mobility, coupled with a decrease in the strength of monsoon circulations (and summer rainfall) in Africa and Asia, thereby increasing sediment availability as vegetation cover and soil moisture decreased. In many areas, increased sediment availability as a result of decreased rainfall and enhanced mobility (as a result of increased wind strength) coincided, resulting in widespread dune formation. However, sand seas in which

the dominant winds are related to the southwest monsoon (especially the Wahiba and Thar sand seas) experienced reduced activity at this time.

The response of low-latitude sand seas to Quaternary climate change is becoming much clearer, in large part as a result of the application of luminescence dating techniques, coupled with new paradigms (especially concepts of dune generations and eolian sediment state) for the geomorphic and sedimentary development of these extensive depositional systems. Future work will be increasingly focused on understanding spatial patterns in the response of sand seas to climate change; the relations between sediment supply, availability, and mobility; and the role of sub-Milankovitch-scale climate change in sand sea evolution.

Glossary

Biogenic ooze: Sediment composed of the remains of surface-dwelling plankton. These sediments are some combination of calcium carbonate, CaCO_3 and biogenic opal, $\text{SiO}_2 \cdot n\text{H}_2\text{O}$.

Hemipelagic mud: Silty sediment delivered to the ocean by rivers and transported off the continental shelf in the water column. The mud grains settle out across the outer continental shelf and the continental slope. This is the sediment that eventually forms shale and mudstone.

Milankovitch variability: Milankovitch hypothesized that variations in the orbit of Earth associated with precession

(at periods of 19 and 23 ka), tilt of the spin axis (41 ka), and eccentricity of the orbit (100 and 400 ka) had a pronounced influence on climate.

Red or pelagic clay: A common seafloor deposit that consists of mineral dust grains and authigenic oxides and hydroxides. These deposits accumulate very slowly and are devoid of all biogenic material except fossil fish teeth.

Spectral analysis: A mathematical technique that identifies nonrandom variability in a sample set and discovers the amount and frequency of such fluctuations.

Introduction

The transport of eolian grains and their deposition in the deep sea has been of interest to scientists for over 150 years, beginning with Darwin's observations made aboard the *Beagle* (Darwin, 1846). Radczewski (1939) examined the reddish quartz grains in the Cape Verde Basin, downwind from the Sahara, and noted the importance of dust transport in bringing those grains to the central Atlantic. Rex and Goldberg (1958) explained the quartz in abyssal sediments of the North Pacific by dust transport from Asia. Since the 1960s, studies of the transport of mineral aerosols have abounded. The reader would find overview papers by Prospero et al. (1983, 2002),

Rea et al. (1985), Duce et al. (1991), Rea (1994), and Grousset and Biscaye (2005) and books by Pèwè (1981), Pye (1987), and Leinen and Sarnthein (1989) to provide useful depictions of the transport and deposition process. More recently, interest in dust transport and deposition has spread to the biologic oceanographic community, with the formulation of the 'iron hypothesis,' which holds that dust supplies the limiting nutrient iron to otherwise unproductive ocean surface waters (Martin, 1990; Martin and Fitzwater, 1988). Research on various aspects of this topic remains vigorous today (Jickells et al., 2005). Dust is also important in understanding the effects of radiative forcing on the Earth and has received considerable attention from atmospheric scientists (Sokolik et al., 2001).

The demonstration that availability of dust varies with the climate of the source region (Prospero and Nees, 1977, 1986; Prospero et al., 1970) caused marine geologists to begin to look down core into the sediments for this useful record of past continental climates. The first such studies were conducted in the North Atlantic, downwind from the Sahara (Parkin, 1974; Parkin and Padgham, 1975; Parkin and Shackleton, 1973). Samthein et al. (1981, 1982) have studied the same system and provided good overviews of the geologic history of Saharan dust deposition (Ruddiman et al., 1989). Clemens and Prell (1990, 1991), Sirocko and Samthein (1989), and Sirocko et al. (1991) have studied the monsoon-related dust transport from the deserts of Arabia to the northwestern Indian Ocean. The work of the authors, some of which is described below, has been largely in the Pacific Ocean and stems from the early studies of Heath and Leinen (Heath, 1969; Leinen, 1989; Leinen and Heath, 1981).

Nature of the Data

Arid and semiarid continental surfaces are the source of dust in the atmosphere and the ocean. Studies of modern climatology show that most of the wind-borne dust transport each year occurs in a few large storms, commonly in the spring or summer. Satellite data are now available that allow us to track a single dust storm from the Sahara to the Caribbean, or the Gobi to California. The dust entrained by these large storms shows a mixture of particle sizes, with the large particles falling out quickly along the transport path, and the fine grains remaining to be transported transoceanic distances. These fine grains end up in the ocean sediments and, in the absence of other sedimentary components, form the red or pelagic clay deposits that characterize half of the area of the deep-sea floor.

Much of the work on eolian sediment has focused on the fundamental sedimentology of the dust: the transport and depositional processes and the history of those processes provided by the deep-sea record. More recently, the geochemistry of dust has played an increasing role in the overall research effort. The overarching goal of paleoclimate studies based on the record of dust deposition is to understand the geologic history of continental climates and the nature and intensity of the zonal wind systems. There are other ways to approach questions of continental climate, but there are no other direct records of the history and patterns of the wind systems (Rea, 1994).

Students of eolian deposition are faced with several problems from the outset. First, dust makes up only 1 or 2% of the $15\text{--}20 \times 10^{15}$ g of terrigenous sediment brought to the oceans every year. This mainly river-borne material becomes the hemipelagic mud (clayey silts that move offshore in suspension) that drapes the continental margins and extends out to sea for unknown distances. Since 1 or 2% of the river loading can overwhelm the eolian signal in a core, one must be certain that sediments used for eolian information are from cores raised far from land or are otherwise shielded from hemipelagic processes. The most useful sediment for paleoceanographic analyses is biogenic ooze, the fossil remains of sea-surface plankton. In such calcite- and/or opal-rich sediments, the dust makes up only a small percent of the total content, and so must be isolated from the bulk sediment by a somewhat lengthy laboratory chemical procedure (Clemens and Prell, 1990; Hovan, 1995;

Rea and Janecek, 1981). Upon completion of the extraction process, the mineral grains are available for determinations of flux (mass accumulation rate – MAR, commonly given in $\text{mg cm}^{-2} \text{ ka}^{-1}$), particle-size analysis, mineralogy, and geochemistry. It is particularly important to ‘clean’ the grains prior to geochemical analysis because the oxide coatings on the particles carry their own geochemical signature. As the MAR values are a product of the weight percent of the dust component, the ambient linear sedimentation rate, and the dry bulk density of the sediment, resulting values depend on the quality of all three determinations. In new or well-cured cores, the sedimentation rate is the least well known of these values; the percent and bulk density values are generally good to $\pm 5\%$ or so.

Interpretation of the Data

The MAR of eolian dust is a good measure of source area aridity. Humid, vegetated regions put very little dust into the air, while semiarid and arid regions supply considerable amounts. There are hyperarid areas, where there is not enough water to break down the continental feldspars into clays, that generate little dust today; such regions have been deflated. We have been able to map the MAR of dust in the deep sea as being based on the sedimentary record (Rea, 1994). These maps are similar to those provided by Duce et al. (1991) based on modern mineral aerosol transport and show dust flux maxima usually in excess of $1000 \text{ mg cm}^{-2} \text{ ka}^{-1}$ downwind of the main source regions in central and eastern Asia, the Sahara and Sahael, and Arabia and the Horn of Africa. Since most of the land is in the Northern Hemisphere, most of the dust is found there too. The South Pacific, South Indian, and Southern Ocean are sites of minimal dust input, on the order of $1 \text{ mg cm}^{-2} \text{ ka}^{-1}$ or less.

Eolian dust has a grain-size distribution that peaks at about $2 \mu\text{m}$, with essentially no material coarser than $10 \mu\text{m}$ (Rea and Hovan, 1995). All the work on eolian grain size has assumed that the grain size is related to the intensity of the transporting wind, but clear evidence of this was not produced until recently when Clemens reported on sediment trap studies in the Indian Ocean, downwind from the Arabian deserts (Clemens, 1998). The size of the dust grains changes very little downwind, after the coarser materials have settled out, such that after perhaps 2000 km from the original dust storm site, the size is uniform. Maps of eolian grain size show this remarkable uniformity of size across the entire North Pacific Ocean (Rea and Hovan, 1995). Another working hypothesis is that these grains are in equilibrium with the transporting winds, and that the stronger winds will transport a coarser equilibrium grain size of material.

There is one more point to make about these data. At the distal locations sampled in our deep-sea cores, the MAR and grain size of dust vary independently. The closest analogy is with the competence and capacity of rivers. A large river like the Mississippi might carry a lot of mud, but it will all be fine grained. Conversely, a mountain stream might move sand and gravel, but not in Mississippi-like quantities. Cross-plots of data from those cores, which have good flux and size information, show no correlation between the two kinds of data (Rea, 1994). This means that the suggestion that more dust and stronger winds are directly related is a misconception.

Spectral analysis of eolian grain size and flux records have demonstrated that both respond to orbital forcing, commonly at the periodicities of ~ 100 ka (reflecting changing eccentricity of the orbit), 41 ka (tilt of the spin axis with respect to the orbital plane), and 20 ka (precession around the orbit), originally calculated by Milankovitch (1941). Milankovitch variability in dust grain-size data was shown originally by Janecek and Rea (1984, 1985). The first detailed study was based on a core from the equatorial Pacific and demonstrated that the variability in the eolian grain-size data was coherent and in phase with a radiolarian-based proxy for upwelling, quantitatively linking wind intensity and equatorial upwelling in this Quaternary core. The main spectral peak in the grain size and upwelling proxy data occurs at about 30 ka, a cross-product of eccentricity and tilt periods rather than one of the primary orbital periods (Pisias and Rea, 1988). Orbital forcing at approximately 30 ka is a common finding in a variety of spectral-analysis studies of atmospheric and surface ocean proxy records (Rea, 1994).

Studies of a North Pacific core directly downwind from the China Loess Plateau documented orbital variability in both the flux data, which matches loess deposition (see below), and the dust grain-size data (Hovan et al., 1991). The dust

accumulation rate record showed spectral power at the primary orbital periods of about 100, 41, and 19 ka, but eolian grain-size data from this same core exhibit spectral peaks at 100, 50, and 25–35 ka (Hovan et al., 1991). Clemens and Prell (1990, 1991) analyzed sediments downwind from the Arabian Desert to understand the monsoonal influence in the Gulf of Arabia. They show pronounced orbital power at the frequencies associated with tilt and precession, along with noticeable power at about 35 and 54–59 ka in the grain-size record. The MAR of eolian dust varies on longer, 100 and 19–23 ka periods. This last observation is important because it means that wind intensity is not linked only to the 100-ka glacial–interglacial cycles of the later Quaternary but varied on shorter periodicities, an observation consistent with the earlier work of Pisias and Rea (1988). The existence of important amounts of variability in the atmospheric transport process at periods other than the primary periodicities determined by Milankovitch (1941) remains a puzzle and is a continuing topic of research.

Much work has concentrated on determining the geochemistry of the dust, as a way to determine both provenance and, if there is a long record, changes in the nature of the eolian source region. Both elemental, largely rare-earth element information

Figure 1 Dust accumulation record spanning the past 500 ka from core V21-146 in the northwestern Pacific Ocean. Loess (L) and soil (S) horizons which are shown at left are from the section at Xifeng. Dust flux maxima faithfully match the loess horizons. $\delta^{18}\text{O}$ records from the core, generated originally by Shackleton, show that dust flux maxima occur at glacial maxima as indicated by heavy values on the isotope curve. The global average isotope curve, the SPECMAP stack, is shown for comparison. Glacial ages are identified with even numbers on the SPECMAP record. Reproduced from Hovan SA, Rea DK, and Pisias NG (1991) Late Pleistocene continental climate and oceanic variability recorded in northwest Pacific sediments. *Paleoceanography* 6: 349–370.

(Olivarez et al., 1991; Weber et al., 1996), and isotopic, based on the isotopes of Nd, Sr, and Pb (Jones et al., 1994, 2000; Pettke et al., 2000, 2002), data have been presented. The first major finding of this work is that maps of the isotopic values of the mineral component of surficial sediments demonstrate that dust from Asia dominates North Pacific seafloor sediments, from China almost all the way east to North America and south to the Intertropical Convergence Zone (ITCZ) (Jones et al., 1994, 2000). North America supplies surprisingly little dust to the North Pacific (Jones et al., 1994, 2000). South of the ITCZ, dust has the geochemical signature of young andesite, implying a Central or South American source. This transition at the ITCZ is of interest because the first good downcore geochemistry on a red clay core, by Kyte et al. (1993), showed a change from a younger Asian source to an older American dust source some time during the late Oligocene. Since the core studied now lies at about 30° N and can be backtracked to about 20° N, this implies that the ITCZ once lay far north of its present location. One of the best examples of using the geochemistry of dust to 'fingerprint' the source regions has been the identification of the source of dust now found in the Antarctic (Argentine Patagonia; Grousset et al., 1992) and Greenland (central Asia; Biscaye et al., 1997) ice cores.

Quaternary Records from the North Pacific

A long-standing and continuing goal of paleoclimatologists is to link together records from the land surface, and the ocean, the main engine of climate change. The primary paleoceanographic record of climate change, linked to every paleoceanographic proxy, is the oxygen isotope record. The classic land record of late Cenozoic climate change is the sequence of loess and soil horizons such as those that cover the Loess Plateau in China. The loess horizons are formed in cold, dusty glacial times, and the soils are the product of warmer and more humid, thus vegetated, interglacials. Loess deposits form a remarkably detailed record of climate in Asia and elsewhere. The only way in which the $\delta^{18}\text{O}$ and loess records can be joined is in a marine core that can be tied to a loess sequence and has a good $\delta^{18}\text{O}$ record. Hovan et al. (1989, 1991) were presented with this circumstance in the form of piston core V21-146 from Shatsky Rise (37°41' N, 163°02' E) in the northwestern Pacific Ocean. The dust MAR record in V21-146 matches well with the loess-soil records from China and enables us to confirm by direct observation that loess maxima occur during the glacial maxima and that, within the accuracy of the data sets, the $\delta^{18}\text{O}$ indication of maximum glaciation matches the loess deposition peak (Figure 1; Hovan et al., 1989, 1991).

Cenozoic Records of Atmospheric Circulation and Continental Climate

All the good, longer records of dust accumulation are from sediment cores that now underlie the North Pacific-prevailing westerlies. The first of these records to have been generated is still the most revealing, that from giant piston core LL44-GPC3 (30°19' N, 157°49' W). Janecek and Rea (1983) determined the 70-million-year-long record of continental aridity and wind intensity from this red clay core. The dust flux data (Figure 2) showed little input in Oligocene and older times, a doubling of the dust flux at about 24 Ma, and a large increase associated

Figure 2 Dust accumulation rate (open circles) and grain size of dust (open squares) and quartz grains (crossed squares) extracted from piston core LL44-GPC3, raised from the central North Pacific Ocean. Size is calculated as median grain size and shown in phi units (ϕ_{50}).

with late Cenozoic cooling and drying of the Northern Hemisphere. It was the grain-size record from this core that provided the important new information in this study. The middle and late Cenozoic grain size shows a coarsening beginning sometime in the late Eocene and continuing, perhaps in steps, until the present. The surprise in this record is the large change in grain size that occurs lower in the core. This large change in dust size occurs in other North Pacific cores and has been dated as occurring exactly at the Paleocene–Eocene boundary (see Rea et al., 1990). It records a remarkable reduction in wind intensity from latest Cretaceous and Paleocene winds similar to present to a regime of very sluggish atmospheric circulation in the Eocene. These data are one of the fundamental pieces of information that underlie the grand quandary of Eocene climate: how, when both atmospheric and oceanic circulation appear sluggish, is it possible to transport enough heat to keep the polar regions warm enough to support crocodiles and palm trees? The question remains unanswered.

The details of late Cenozoic Asian aridity and wind intensity are best found in sediments recovered at North Pacific ODP Site 885/886 (44°41' N, 168°15' W). The section recovered at Site 885/886 is in biogenic ooze with a good magnetic reversal stratigraphy and so has far better age control than do the red clay cores farther south. Information from this site (Figure 3; Rea et al., 1998) shows a number of important aspects of late Cenozoic climate change. First, the dust flux data show an order of magnitude increase at 3.6 Ma, 1 My before the onset of major Northern Hemisphere glaciation at about 2.6 Ma.

Figure 3 Dust accumulation rate (open circles) and grain size (solid squares) for the past 12 My from the North Pacific. Size is calculated as median grain size and shown in phi units (ϕ_{50}).

This increase reflects the rapid drying of the central Asian basins north of the Tibetan uplift, as these regions were cut off by the rising plateau from their Indian Ocean moisture supply. Other work has shown that conglomeratic sediments sweep north from the north edge of the Tibetan Plateau at this time, a clear indication of rapid uplift then (Fang et al., 2005; Zheng et al., 2004).

The eolian grain-size information from Site 885/886 tells a different story. Size and flux data vary independently from each other, as noted above. The record from this site, along with that from GPC3, is a good example of this at longer timescales. The grain-size data show that the increase in late Cenozoic wind intensity, presumably a response to high-latitude cooling, begins to increase at about 4.5 Ma, 1 My before the dust flux increased. Together, these records show that Northern Hemisphere glaciation did not occur suddenly and without prior indications of change. Rather a series of events, perhaps 2 or 3 My in duration, led up to the rapid buildup of continental ice sheets at about 2.6 Ma.

Summary

Dust forms only a small percentage of the sediment of the ocean floor, but in broad regions away from continents, the terrigenous component of deep-sea sediment is dominated by dust. These materials provide several kinds of paleoenvironmental information: a history of the aridity of the eolian source region in the MAR data, a history of the strength of the transporting winds in the grain-size data, a record of provenance in the dust geochemistry and knowing provenance, the nature of past zonal winds. There is no other kind of direct proxy for the

nature of past atmospheric circulation (Rea, 1994). As the atmosphere is responsible for half of the global heat transport, this kind of information is particularly valuable in paleoclimatic reconstructions.

Introduction

A fission track is a linear region of intense radiation damage formed by the passage of an energetic, charged nuclear particle through an insulating solid. According to a popular hypothesis, known as the 'ion explosion spike' model ([Fleischer et al., 1975](#)), the charged particle collides with atoms in its path, displaces them and removes their electrons, producing a narrow zone rich in positive ions, which repulse each other into interstitial positions and form vacancies. An elastic adjustment of the crystal or glass then occurs, straining the undamaged matrix ([Fleischer, 2004](#)). Another idea, called the 'thermal spike' model, sees the fast-moving fission fragment producing intense heat along its trajectory. After passage of the charged particle, the track core is quenched by heat loss to the adjacent lattice, leaving it in a disordered state. According to [Chadderton \(2003\)](#), it is likely that both mechanisms are involved in track formation. Maximum density damage exists at the site of fission and decreases to the track termini. This damaged zone persists in the solid after the fission fragment has come to a rest and is called a latent track. Its length is equal to the sum of the range of the two charged particles formed by nuclear fission, each moving in opposite directions. ^{238}U fission events form latent tracks that are 6–10 nm wide and 10–20 μm long and

account for most tracks in natural, terrestrial materials. Latent tracks can only be observed with a transmission electron microscope but can be made visible by chemical etching ([Young, 1958](#)) and readily seen under an optical microscope. Etching takes place by rapid dissolution of the disordered region of the track core, which exists in a state of higher free energy than the undamaged material. As can be seen in [Figure 1](#), the shape of the etched fission tracks varies in different materials, due mainly to differences in symmetry and magnitude of the difference between the track and bulk etch rates. Fission tracks in glass are relatively wide, conical pits due to its isotropic properties and a track etch rate that is not much greater than the bulk etch rate. Micas have diamond-shaped tracks, whereas tracks in zircon and apatite are needle-like because of the large difference between track and bulk etch rates, the former being much greater.

Fission tracks have varied uses ranging from applications in the fields of engineering, medicine, nuclear physics, and space sciences to the earth sciences ([Fleischer, 1998](#)). The most important applications in the earth sciences are thermochronology ([Reiners and Ehlers, 2005](#)) and geochronology. Thermochronology – the more active field at present – focuses on understanding the thermal history of rocks and duration and rates of geological processes, such as crustal uplift.

Figure 1 Fission tracks in glass shards, mica, and zircon. (a) Fission tracks (6–8 µm wide) in glass shard as seen using an optical microscope; (b) SEM image of fission tracks in glass shard (darker areas are the deepest part of the conical pits); (c) fission tracks in mica (~5 µm wide); (d) needle-like fission tracks in zircon from the Bishop Tuff, California (crystal is ~0.2 mm wide).

Geochronology, on the other hand, is primarily concerned with formation age, the topic of interest to us here.

Zircon and glass are the most suitable phases for dating Quaternary deposits by fission-track (FT) methods, although apatite and sphene may also be useful. The most desirable situation for dating Quaternary sediments is where they are associated with silicic tephra beds because not only can they be reliably dated using their zircon and glass shards, but their widespread distribution and common distinctiveness make tephra beds excellent markers, linking the stratigraphies of isolated sites, sometimes over distances exceeding 1000 km (see [Major Scale Forms](#)).

We outline in this article the basic principles of FT dating, detail the different methods used for glass and zircon, describe the correction procedures for partial track fading (PTF) in glasses, comment on the accuracy and precision of FT dates, and compare the results obtained to those of other dating methods, especially the $^{40}\text{Ar}/^{39}\text{Ar}$ technique. Finally, we illustrate the application of FT dating to the Quaternary Sciences by reference to a few case studies.

Age Equation

In principle, FT dating is similar to other radioisotopic dating methods except that the decay product of interest is the spontaneous fission track, not the daughter nuclide. If the rate of

decay of ^{238}U by spontaneous fission is known (the decay constant, λ_F), then we need only to know the U concentration and abundance of spontaneous fission tracks, assuming all are preserved, to calculate an age ([Price and Walker, 1963](#)). The basic age equation for an FT age, t , given by [Wagner and Van den haute \(1992\)](#) is:

$$t = 1/\lambda_D \ln \{1 + (\lambda_D/\lambda_F)(\rho_s/\rho_i)QGI\sigma_F\varphi\} \quad [1]$$

where λ_D is the total decay constant for ^{238}U ($1.551 \times 10^{-10} \text{ year}^{-1}$), λ_F is not well determined (values cluster around $7 \times 10^{-17} \text{ year}^{-1}$ and $8.5 \times 10^{-17} \text{ year}^{-1}$; [Bigazzi, 1981](#)), ρ_s is the areal track density of etched spontaneous tracks, ρ_i is the areal track density of etched induced fission tracks, Q is a procedural factor involving track registration and observation efficiency ($Q=1$ if track etching and counting procedures are identical), G refers to the initial geometry ratio of the etched surfaces for counting spontaneous and induced tracks ($G=1$ or 0.5 depending on the dating procedure used), I is the isotopic abundance of $^{235}\text{U}/^{238}\text{U}$ (7.2527×10^{-3}), σ_F is the cross section for induced nuclear fission of ^{235}U by thermal neutrons ($580.2 \times 10^{-24} \text{ cm}^2$), and φ is the thermal neutron fluence, measured by the induced FT density on a U-doped glass (e.g., NIST 612), ρ_D , irradiated together with the sample, and is equal to $B\rho_D$, where B is a calibration constant that is empirically determined. The irradiation procedure is used to enable the U concentration to be determined through the known relative abundance of ^{235}U – ^{238}U because only ^{235}U fissions when

irradiated with thermal neutrons. Hence, given these constants, an FT age is obtained by measuring three areal track densities, ρ_s , ρ_i , and ρ_D . Due to the uncertainties in the values of λ_F and σ_F , and the dependency of φ on the nuclear reactor characteristics, especially the degree of thermalization, use of the zeta calibration based on analysis of age standards was recommended by Hurford and Green (1983) and is now widely used. The zeta age calibration factor, ζ , is defined by:

$$\zeta = B(I\sigma_F/\lambda_F) \quad [2]$$

Substituting eqn [2] in eqn [1], and considering $G=1$ and $Q=1$, gives:

$$t = 1/\lambda_D \ln \{1 + \lambda_D(\rho_s/\rho_i)\zeta\rho_D\} \quad [3]$$

Rearranging eqn [3] for a standard of known age (t_{std}) gives:

$$\zeta = \{ \exp(\lambda_D t_{std}) - 1 \} / \{ \lambda_D(\rho_s/\rho_i)_{std} \rho_D \} \quad [4]$$

The value of ζ can then be used in eqn [3] to give the age of a sample.

If the grains within a sample have a common age, the uncertainty on the age is given by (Green, 1981):

$$\sigma(t)/t = \{ 1/N_s + 1/N_i + 1/N_D + [\sigma(\zeta)/\zeta]^2 \}^{1/2} \quad [5]$$

where $\sigma(t)$ is the $\pm 1\sigma$ uncertainty on the age, $\sigma(\zeta)$ is the $\pm 1\sigma$ uncertainty on ζ ; N_s , N_i , and N_D are the total number of tracks counted for ρ_s , ρ_i , and ρ_D , respectively, and the area is determined using an eyepiece graticule. If the area is estimated by use of the point-counting technique, commonly the case with glass shards, an additional experimental error is involved. In this case, the relative standard error (se) on the age (t) is given by (Bigazzi and Galbraith, 1999):

$$se(t)/t \approx \{ 1/Y_s + [1 - (X_s/n_s)]/X_s + 1/Y_i + [1 - (X_i/n_i)]/X_i + 1/Y_D \}^{1/2} \quad [6]$$

where Y_s , Y_i , and Y_D are the total number of spontaneous and induced tracks counted in the sample, and the number of tracks counted in the fluence monitor, respectively. X_s and X_i are the total number of points on glass in determining ρ_s and ρ_i , and n_s and n_i are the corresponding totals for the fields of view.

Prerequisite Conditions for FT Geochronology

The mineral or glass to be dated by the FT method must meet several criteria (Dumitru, 2000; Faure, 1977). The U concentration must be sufficient to give a statistically significant age. Tracks, once formed, must be stable at ambient temperatures and not fully anneal soon after formation. Partial fading of tracks is common in some minerals and glasses, but correction procedures have been developed to account for this condition, particularly in glass. Ideally, the material should be free of microlites and other inclusions, defects, and lattice dislocations, which, upon etching, can resemble fission tracks and make track identification and counting difficult (Storzer and Wagner, 1982). The crystal or glass surface area must be large enough to permit an accurate measurement of the areal track densities. For example, the pumiceous grains in Figure 2(a) cannot be dated, but the poorly vesicular, blocky glass shards in Figure 2(b) can be readily dated by fission tracks. The lower limit in grain size is $\sim 80 \mu\text{m}$. Ideally, U must be distributed uniformly throughout

Figure 2 (a) Pumiceous grains from the late Pleistocene Sheep Creek-K tephra, Yukon, Canada. (b) Poorly vesicular, blocky glass shards of the middle Pleistocene Gold Run tephra, Yukon, Canada. Sheep Creek-K tephra cannot be dated by glass FT methods because of insufficient glass surface area. Gold Run tephra, on the other hand, is readily dated by fission tracks (Table 1).

the material. In some materials, this requirement can now be assessed directly by laser ablation inductively coupled plasma-mass spectrometry (LA-ICP-MS) (Pearce et al., 2004). The EDM of FT dating, described below, can compensate for the inhomogeneous U distribution typical of minerals such as zircon. The sample must not have suffered any post-emplacement (depositional) heating that would cause resetting of its fission tracks. The nature of the sample's geologic environment would offer insights on the likelihood of such an event, as does the size distribution of its spontaneous tracks. The mineral or glass must be unaltered and form a primary constituent of the rock or sediment being dated. For example, tephra deposits, commonly dated by the FT method, typically contain foreign grains of xenocrystic, lithic, and detrital origin, which must be avoided during the track-counting operation. This requires use of grain-specific methods for FT counting. As with all geochronologic studies, the stratigraphic, and, in some cases, sedimentologic context of the deposit must be well established. Materials that satisfy these criteria are glass (obsidian, tektites, volcanic glass shards, and glasses made by humans), zircon, apatite, and sphene, although the

latter two are seldom used to date Quaternary events because of low U and rarity.

Glass-FT Methods

General Considerations

One of the earliest successful examples of FT dating involved the use of glass shards to determine the age of Bed 1 at Olduvai Gorge (Fleischer et al., 1965a,b). The FT age of 2.0 ± 0.3 Ma agreed with the K–Ar age of 1.75 ± 0.05 Ma, obtained earlier by Leakey et al. (1961). Silicic, hydrated glass shards are an ideal medium for FT dating. They are the most abundant phase of tephra beds; they are mostly homogeneous and seldom contain microlites or inclusions; they are isotropic with uniform etching characteristics; U contents typically range from 2 to 8 ppm for rhyolitic to dacitic glasses, enough to produce a sufficient number of spontaneous tracks for a statistically useful Quaternary age; rapid cooling during the eruption and subsequent storage at near-surface temperatures mean that acceptable formation ages can be obtained; proven correction methods for PTF exist; and glass shards as small as ~ 80 μm can be dated, opening up the geochronology of regions distant from volcanic centers (especially those of calc–alkaline composition where K-rich minerals are rare) because their parent silicic tephra beds are commonly very widespread. It must be admitted, however, that FT dating late Quaternary events by rhyolitic glass shards is a challenge, although possible, if long counting times are accepted (e.g., Kohn, 1979; 20.3 ± 7.1 ka), or the glass is unusually rich in U (Alloway et al., 2004b; 50 ± 3 ka). Similarly, glass shards of andesitic and basaltic composition commonly have U contents < 1 ppm U and cannot be used to date Quaternary events. Obsidians are much more suitable in this respect because of the large surface areas for counting that are available. Bigazzi and Bonadonna (1973) dated Lipari obsidians in the range of 1.4–11.4 ka, and U-rich archaeological glasses of late historic age have been dated by fission tracks (Wagner and Van den haute, 1992).

Whereas the problem of contamination in obsidian and tektite glasses is negligible, it is an issue when FT dating glass shards and zircon from tephra beds, which are very susceptible to reworking (Figure 3). Grain-specific methods for compositional characterization and FT dating must be used to neutralize this problem. Tight compositional clustering of glass shards, as seen in Old Crow tephra (Figure 4), show little if any contamination, but compositional outliers exist in the Dominion Creek tephra and must be addressed before an accurate FT age can be determined (Figure 4). In the latter case, the contaminating glass shards possessed a notably higher track density, allowing them to be recognized and ignored. Samples that show multiple compositional clustering due to magma-mixing or post-depositional reworking cannot be reliably dated by glass-FT methods. Samples with minor contamination are tractable, however, because glass-FT dating methods are grain-specific in that the track data are accumulated by examination of individual grains so that any foreign glass shards that are encountered during the counting process can be ignored. In such cases, the exotic glass would have to have an age and composition that is very different to that of the

Figure 3 Photograph of Huckleberry Ridge tephra. The lower part of the bed is primary air-fall tephra with horizontal bedding. The upper, cross-bedded part is reworked material washed into the site, and is, therefore, more likely to be contaminated by detrital grains. Scale is mm ruler. Photograph by Glen A. Izett.

host tephra, resulting in a distinctive areal density and size of their fission tracks.

A unimodal major-element composition of glass shards in a sample (e.g., Old Crow tephra, Figure 4) argues for U homogeneity. However, a direct measurement of U homogeneity on a shard-to-shard basis can now be made by LA-ICP-MS (Pearce et al., 2004), and two examples are shown in Figure 5. Uranium contents range from 4 to 12 ppm for both the Lava Creek B and Huckleberry Ridge tephra beds with the average U values obtained by solution ICP-MS and LA-ICP-MS being very similar. In FT dating, U is conventionally measured by irradiating an aliquot of the sample with a specified dose of thermal neutrons that induce fission of a portion of the ^{235}U , which can then be used to determine the amount of ^{238}U in the sample because the ratio of ^{238}U – ^{235}U is a fixed number (I in eqn [1]). Thousands of glass shards are scanned to give ρ_i so that a very good average value of the ^{238}U content is obtained, despite the large range in U values seen in Figure 5. Further, ρ_s is determined under identical conditions so that ρ_s/ρ_i in age eqn [1] can be regarded as accurately determined, and proven to be so by the excellent agreement between corrected glass-FT and $^{40}\text{Ar}/^{39}\text{Ar}$ dating methods for Huckleberry Ridge tephra (1.97 ± 0.22 and 2.003 ± 0.014 Ma, respectively). In a recent development, FT ages of apatite grains are now being determined using U concentrations determined by LA-ICP-MS (Hasebe et al., 2004). Future investigations should explore the viability of this approach for glass shards, obsidians, and tektites, using both average U values from a large number of LA-ICP-MS analyses as well as solution ICP-MS.

There is only one formally accepted glass age standard, Moldavite (Balestrieri et al., 1998). Because the I.U.G.S. Subcommittee on Geochronology specified the use of splits from a single Moldavite (Hurford, 1990), and no supplier is known who can provide a sample large enough for distribution to the FT community, in essence, no formal glass age standard presently exists! Other necessary attributes of a formal age standard are that it contains sufficient tracks to give a statistically meaningful age, and that it has not suffered from PTF. Whether such a glass exists or not is debatable. The candidate that comes closest to these requirements is the Jankov Moldavite. Other potential age

Figure 4 Oxide-variation diagrams showing major-element composition of glass shards from late Pleistocene Old Crow and Dominion Creek tephra beds, Yukon Territory, Canada. Tight clustering in Old Crow tephra demonstrates that contamination is very minor, if present. Several compositional outliers occur in Dominion Creek tephra indicating presence of contamination that must be addressed before an accurate FT age can be obtained. N is the number of individual glass-shard microprobe analyses.

Figure 5 U and Th contents in glass shards from Lava Creek B and Huckleberry Ridge tephra beds, USA, as determined by LA-ICP-MS. Average values for these elements given by solution ICP-MS are shown by pink circle (HRT) and pink oval (LCBT). Average U concentrations by each method are very similar: HRT – 8.2 ppm by LA-ICP-MS, 6.7 ppm by solution ICP-MS; LCBT – corresponding values are 7.4 and 7.5 ppm. Agreement in the average Th values by these two methods is obviously not as good.

standards recommended by Balestrieri et al. (1998) are Roccastrada R2V, Mancusanite, and the Japanese glass JAS-G1. The University of Toronto Laboratory currently uses the Huckleberry Ridge tephra from Meade County, Kansas, USA, to monitor accuracy of its FT age determinations (Table 1). This tephra bed has large glass shards with no inclusions, high U content (Figure 5), an $^{40}\text{Ar}/^{39}\text{Ar}$ age of 2.003 ± 0.014 (2σ) Ma (Ganseccki et al., 1998), and abundant spontaneous fission tracks, making it a useful informal reference glass. PTF has occurred in its glass shards ($D_s/D_i = 0.81 \pm 0.03$ based on five samples; no laboratory heat treatment), but well-established correction procedures are available (see below).

Population FT Method

The glass-population method can be used for homogeneous samples. In the case of glass shards, the coarsest, least vesicular fraction is obtained using sieves combined with magnetic and heavy-liquid techniques. Obsidian and tektite samples are gently crushed and sieved to concentrate the 0.25–0.125 mm fraction. The sample is split into two aliquots, one of which is heated to remove the spontaneous tracks and irradiated. Both aliquots are then mounted on glass slides with epoxy, polished

Table 1 Glass-fission-track age of Gold Run tephra, Klondike goldfields, Yukon Territory, Canada

Ages calculated using the zeta approach and $\lambda_D = 1.551 \times 10^{-10} \text{ year}^{-1}$. Zeta value is 318 ± 3 based on six irradiations at the McMaster Nuclear Reactor, Hamilton, Ontario, using the NIST SRM 612 glass dosimeter and the Moldavite tektite glass (Lhenice locality) with an $^{40}\text{Ar}/^{39}\text{Ar}$ plateau age of $15.21 \pm 0.15 \text{ Ma}$ (Staudacher et al., 1982). Standard error ($\pm 1\sigma$) on age estimate is calculated according to Bigazzi and Galbraith (1999). Weighted mean age based on UT1791^a and UT1907^c. Area estimated using the point-counting method (Naeser et al. 1982). D_s = mean spontaneous track diameter, D_i = mean induced track diameter. Number of tracks counted is given in brackets. Number of tracks measured given in square brackets. The single-crystal (sanidine) laser-fusion $^{40}\text{Ar}/^{39}\text{Ar}$ age of Huckleberry Ridge tephra, the internal standard, is $2.003 \pm 0.014 \text{ Ma}$ (2σ error) (Gansecki et al. 1998). The low value of D_s/D_i for UT1366 and its associated small error suggest that the plateau condition was not reached, although the calculated age is very close to its $^{40}\text{Ar}/^{39}\text{Ar}$ age. The population-subtraction method was used. These glass-fit ages have not been corrected according to our new calibration scheme. See notes in Table 4.

^aSample corrected for partial track fading by the track-size (DCFT) method (Sandhu and Westgate, 1995); uncorrected age noted simply by sample number.

^cSamples corrected for partial track fading by thermal pretreatment, the ITPFT method (Westgate, 1989); samples heated for 30 days at 150°C .

to expose internal surfaces within the grains, and etched in HF to reveal the tracks. The spontaneous areal track density, ρ_s , is obtained from the unheated shards, and ρ_i from the heated, irradiated shards. Acceptable ages were determined on the Macusanite obsidian using this method (Osorio et al., 2003), the samples being heated for 10 h at 560 °C in order to erase the spontaneous tracks. However, for a number of reasons, this method is not recommended for hydrated glass shards. The differential heat treatment means that track-etching efficiencies for ρ_s and ρ_i are different. Heating above 200 °C drives off water and produces brittle glass shards, which fracture easily when polished, thereby reducing the glass surface area available for counting because of the larger surface area exposed to chemical attack during etching. Crazed surfaces are also produced and hinder track recognition (Naeser et al., 1980).

Population-Subtraction Method

The important distinction of this method is that the two aliquots are not subjected to any heat treatment prior to irradiation. The induced areal track density, ρ_i , is calculated by determining the areal track density of the irradiated sample and then subtracting ρ_s . An example of a FT age determination using this method is shown in Table 1, which also demonstrates the information that should be provided in the documentation of a glass-FT age determination.

Correction Methods for PTF in Glasses

Introduction

When a glass or mineral with latent tracks is held at high temperatures for a sufficient period of time, the disordered structure becomes restored, presumably by a diffusion mechanism. A number of factors influence the stability of latent nuclear tracks in solids, but temperature is by far the most important (Fleischer et al., 1965a,b). As latent tracks are progressively heated, they gradually shorten. For internally distributed tracks, the observed areal track density at a surface depends on the etchable length of the tracks and so this length reduction is accompanied by an areal track density reduction. Thus, if the range of spontaneous fission tracks has been lowered by heating, the calculated age will be younger than the true age. Glasses suffer from PTF, which can occur even at ambient surface temperatures (Naeser et al., 1980), so that it is always necessary to apply a correction for this fading effect before a meaningful FT age can be obtained.

Track-Size Correction Methods

The track-size correction method involves measuring the diameters of spontaneous tracks in the natural sample and comparing them to the diameters of induced tracks in the irradiated aliquot. If the mean track diameter of spontaneous tracks, D_s , is less than the mean diameter of induced tracks, D_i , PTF must have affected the sample (Figure 6). A correction for the lowered areal track density is made by reference to a calibration curve, which shows the correlation between reduction in areal track density, ρ/ρ_o , to reduction in mean track diameter, D/D_o , where ρ_o and D_o are the original areal track density and mean track diameter, respectively. The points defining this curve are derived from a series of

annealing experiments on the irradiated aliquots (Arias et al., 1981; Storzer and Wagner, 1969). Sandhu and Westgate (1995) developed a modified version of the size correction method in which apparent ages of glass shards from tephra beds are corrected for PTF by using a 1:1 relationship between ρ/ρ_o and D/D_o – an approach supported by experimental data. If the sample is etched to give D_i in the range of 6–8 μm , the corrected spontaneous areal track density (ρ_{sc}) is given by:

$$\rho_{sc} = \rho_s(D_i/D_s) \quad [7]$$

The near-linear relationship observed by Sandhu and Westgate (1995) contrasts sharply with the distinctly nonlinear correlation found by Storzer and Wagner (1969; Figure 7). Van den haute's study (1985) explains this difference as due to the different etching conditions used. He theoretically calculated a set of curves showing how ρ/ρ_o varies with D/D_o with progressively longer etch times (i.e., increase in h , the thickness of the glass layer removed by the etchant). At low values of h , the curves are strongly nonlinear, but become near-linear with larger values of h (Figure 7). According to these data, the average track diameter in Storzer and Wagner's study (1969) is $\sim 5 \mu\text{m}$, whereas Sandhu and Westgate (1995) etched their glasses to give a mean track diameter in the range of 6–8 μm .

Plateau Correction Methods

The step-heating plateau method (Storzer and Poupeau, 1973) takes advantage of the higher thermal stability of partially faded spontaneous tracks. The FT age of a sample is proportional to ρ_s/ρ_i . If PTF has occurred, this ratio will be too low. However, when pairs of the natural sample and its irradiated aliquot are heated together for a given time at progressively higher temperatures, ρ_s/ρ_i increases until a plateau level is reached. The value of ρ_s/ρ_i at this plateau level is used to give an FT age corrected for PTF. An example of this approach is given in Arias et al. (1981). An alternative method is to keep a constant temperature and change the heating time (Burchart et al., 1975). An excellent example is the work of Bonetti et al. (1998) on an Australian obsidian (Figure 8). The steady increase in apparent age with continued heating at 140 °C is clearly shown, as is the plateau condition, which is reached after 50 h and indicates an age of 85 Ma. Attainment of the plateau condition is also shown by $D_s/D_i = 1$. A modified version of the plateau technique has been developed by Westgate (1989), who showed that a single heat treatment of 150 °C for 30 days is sufficient to correct fully for PTF. Again, the plateau position is recognized by $D_s = D_i$. In practice, an error is associated with D_s/D_i . For example, taking eight recently determined glass-ITPFT ages, the range in D_s/D_i values is 1.03–0.94 with a mean value of 0.99 ± 0.03 . This procedure has been successfully applied to hydrated, silicic glass shards of many tephra beds, as noted below. Following up on this work, Kitada and Wadatsumi (1995a) showed that by increasing the temperature to 165 °C only a 5-day heat treatment was needed to give a plateau age (Figure 9). Other workers have used different time-temperature combinations to reach the plateau (Table 2). Plateau-annealing conditions should be such as to ensure minimal structural damage to the glass with no deleterious effects on its etching characteristics. Consequently, a

Figure 6 Size frequency curves of FT diameters in glass shards from the Huckleberry Ridge and Gold tephra beds showing partial track fading. DCFT samples unheated; ITPFT samples heated 150 °C for 30 days. (a) Mean track diameter of spontaneous tracks is $5.98 \pm 0.06 \mu\text{m}$ ($n=329$); mean diameter of induced tracks is $7.63 \pm 0.09 \mu\text{m}$ ($n=597$), $D_s/D_i=0.78 \pm 0.01$. Corresponding values for other samples are: (b) $6.41 \pm 0.19 \mu\text{m}$ ($n=50$), $6.41 \pm 0.11 \mu\text{m}$ ($n=199$), 1.00 ± 0.03 ; (c) $5.39 \pm 0.10 \mu\text{m}$ ($n=155$), $6.24 \pm 0.06 \mu\text{m}$ ($n=848$), 0.86 ± 0.02 ; (d) $6.46 \pm 0.18 \mu\text{m}$ ($n=94$), $6.81 \pm 0.09 \mu\text{m}$ ($n=398$), 0.95 ± 0.03 .

Figure 7 Calculated curves (solid lines) representing the annealed to unannealed ratio of mean track diameter versus areal track density for different etching conditions in an internal glass surface. The thickness of the glass layer removed by the etching is h , and R is the etchable range of track of a single fission fragment. Experimental curves of Storzer and Wagner (1969) and Sandhu and Westgate (1995) are indicated by the dashed lines. Modified from Van den haute P (1985) The density and the diameter of fission tracks in glass with respect to age interpretation. *Nuclear Tracks* 10: 335–348.

low temperature–long time combination is favored, although, in the light of the data shown in Table 2, a heating period of over 15 days at 150 °C is probably excessive.

Comparison of Glass-FT Ages Corrected by the Diameter and Plateau Methods

Glass-FT ages have been determined for many tephra beds at the University of Toronto FT Laboratory using the diameter-correction (glass-DCFT) method of Sandhu and Westgate (1995) and isothermal plateau (glass-ITPFT) method of Westgate (1989; Table 3, Figure 10). Excellent agreement exists, adding confidence to the validity of both methods. Optimal etch times are longer for samples that have been heated, as in the ITPFT method, and limit application of this method to glass shards $\geq 120 \mu\text{m}$. On the other hand, glass shards as small as $\sim 80 \mu\text{m}$ can be dated by the DCFT technique, which requires no heat treatment.

Accuracy and Precision of Glass-FT Ages

The glass-FT ages shown in Table 4 range from 50 to ~ 15 Ma. All are within $\sim 5\%$ of the age determined by other methods, mainly $^{40}\text{Ar}/^{39}\text{Ar}$, and also K–Ar, thermoluminescence, ^{14}C , zircon FT, and orbitally tuned ages (Table 5). In particular, both the DCFT and ITPFT ages on reference glasses mentioned by Balestrieri et al. (1998) agree very well with the $^{40}\text{Ar}/^{39}\text{Ar}$

Figure 8 Plateau age for Australian obsidian AU602 obtained by using isothermal treatment at $T = 140^\circ\text{C}$ (upper). Induced and spontaneous FT diameters at each step of thermal treatment (lower). Plateau age of 85 Ma is reached at 50 h when $D_s/D_i = 1$. Reproduced from Bonetti R, Guglielmetti A, Malerba F, Migliorini E, Oddone M, and Bird R (1998) Age determination of obsidian source samples from North Queensland and New South Wales, Australia. In: Van den haute P and De Corte F (eds.) *Advances in Fission-Track Geochronology*, pp. 305–312. Dordrecht: Kluwer. Copyright 1998, with kind permission of Springer Science and Business Media.

results. The glass surface area in all these samples was estimated by the point-counting technique, so that the se on each glass-FT age is calculated from eqn [6] (Bigazzi and Galbraith, 1999). For the most part, the $\pm 1\sigma$ uncertainty is $\leq 10\%$. An improved precision can be achieved if the sample is dated by several persons, a weighted mean and associated error being determined by the standard inverse variance method. It can be seen, therefore, that glass-FT methods can be successfully applied to volcanic glass shards, obsidians, and tektites, giving accurate and precise ages. Of special note, these grain-specific methods are ideally suited to the dating of distal tephra beds, which are typically thin, discontinuous, fine grained, and contaminated by detrital material. They will greatly facilitate the development of detailed chronologies of tephra-bearing sedimentary sequences located far from volcanic centers.

Zircon Fission-Track Method

As with glass, zircon fission-track (ZFT) dating is a grain-specific method in which individual grains are scanned and counted, making it easier to recognize and eliminate contaminating grains (Figure 11). For zircon, an age is obtained on each

grain that is counted. If there is a statistically significant difference in age between the primary and contaminating grains, the latter can be identified by their anomalous ages and eliminated from the analysis (e.g., Galbraith, 1990; Galbraith and Green, 1990; Kowallis, 1988; Seward and Kohn, 1997). Attached glass is a good indicator of a primary zircon (Figure 11), but euhedral zircons are not necessarily primary because they can retain their euhedral form through several erosional cycles.

Zircon has several advantages over glass for FT dating, mainly its significantly higher annealing temperatures. Fission tracks in glass can fade at ambient surface temperatures (Naeser et al., 1980; Seward, 1979; Seward and Kohn, 1997), resulting in an anomalously young age, but zircon does not begin to lose tracks until temperatures of $\sim 160^\circ\text{C}$ or higher, depending on the duration of heating and the α -radiation damage in the zircon (Brandon et al., 1998). Zircon has the added advantage that it can still be dated after glass has altered to clay. On the other hand, it is not present in all tephra beds—silicic tephra beds are more likely to yield usable zircons than mafic tephra deposits. Furthermore, zircons may be too small ($\sim 80\ \mu\text{m}$) to be dated by fission tracks, particularly in tephra beds sampled far from their source vents, and, because zircon is so rare in tephra deposits, much larger samples need to be collected compared to glass. If tephra beds are being sampled from drill cores, glass is probably the only phase that can be dated with fission tracks because of the limited amount of material available.

Unlike glass, zircons from a single source tend to have a very inhomogeneous U distribution, both within and between individual crystals, and therefore U content must be determined from exactly the same area of a crystal in which spontaneous tracks are counted. This is accomplished using the EDM (Naeser and McKee, 1970; Figure 12). In the EDM, spontaneous tracks are etched, normally in a eutectic KOH–NaOH melt (Gleadow et al., 1976), and counted in the image of the crystal recorded in a plastic or low-U ($<10\ \text{ppb}$) muscovite detector that was in direct contact with the crystal during neutron irradiation (Figure 13). An age is obtained for each grain that is analyzed, but experience indicates that a minimum of six grains should be dated to determine a sample age. Seward and Kohn (1997) recommend that for young zircons with low-track densities, at least 20 crystals should be dated. An alternative method of determining U content by LA-ICP-MS is being developed in several laboratories (Cox et al., 2000; Donelick et al., 2005; Hasebe et al., 2004). LA-ICP-MS eliminates the need for neutron irradiation.

Precautions are necessary when dating zircon, particularly from young tephra beds. Care must be taken to ensure that tracks are fully etched because even slight underetching can result in ages that are too young (Gleadow, 1980; Kohn et al., 1992; Naeser et al., 1987; Seward and Kohn, 1997). This is a common pitfall in dating young, low-track-density zircons in which the lack of tracks makes it difficult to judge correct etching time. A solution suggested by Gleadow (1980) is irradiating a separate test mount of zircons from the sample with ^{252}Cf tracks and then etching the two mounts together, using the ^{252}Cf tracks to determine correct etching time. Zircon populations in young samples typically include many grains with no spontaneous tracks. It is critical that induced-track

Figure 9 Arrhenius plot of FT annealing experiments for Clearlake glass from Fleischer et al. (1968) showing positions of (a) annealing conditions for glass shards used by Westgate (1989), and (A) annealing conditions used by Kitada and Wadatsumi (1995a). Reproduced from Kitada N and Wadatsumi K (1995a) Annealing properties of natural glass fission tracks at the controlled temperature and its implication on the isothermal plateau dating technique. *Journal of Geosciences, Osaka City University* 38: 4.

counts from these grains be included in the age calculation. Zero-track grains are a real part of low-track-density zircon populations. Failure to include them can result in a calculated age that is significantly older than the true age. A classic illustration is provided by the early attempt to date the ~1.9 Ma KBS Tuff (Gleadow, 1980; Hurford et al., 1976).

The precision of zircon and glass-FT ages is similar, and larger than the typical precision on K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ ages, which can be a few percent or less, depending on the material dated and the age of the sample (McDougall, 1995; Table 6 and 7). However, one of the advantages of fission tracks is that many tephra beds that do not contain suitable material for K–Ar or $^{40}\text{Ar}/^{39}\text{Ar}$ dating can be dated by FT using glass and/or zircon.

Applications

New Zealand

Quaternary sequences in New Zealand and in surrounding oceans up to a distance of 1000 km contain abundant silicic tephra beds erupted from the Taupo Volcanic Zone (TVZ) in central North Island (e.g., Shane, 2000). The TVZ is considered to be the most active rhyolitic center on Earth and has been the locus of numerous large ($>100\text{ km}^3$) caldera-forming ignimbrites and plinian eruptions. Dispersal of volcanoclastic material around the TVZ is strongly controlled by prevailing westerly winds, position of fluvial drainage systems, and Mesozoic-aged axial ranges forming topographic obstructions (Figure 14). In New

All ages in Ma unless otherwise noted. Error given is $\pm 1\sigma$. All ages determined at the University of Toronto FT Laboratory.

Zealand, the predominant tropospheric westerly winds promote dispersal of tephra toward the east coast region of North Island and beyond into the adjacent Pacific Ocean. In sedimentary basins (e.g., Wanganui Basin) located adjacent to the TVZ and outside the main atmospheric dispersal axis, the tephra record is dominated by water-supported mass flow, hyperconcentrated flow, and fluvially transported deposits, which can be considered near-contemporaneous with the proximal eruptive deposits.

In New Zealand, FT dating of tephra and pumice-rich horizons has traditionally played a significant role in advancing the stratigraphy and chronology of Plio–Pleistocene sediments in the southern half of the North Island (e.g., Boellstorff and Te Punga, 1977; Milne, 1973; Seward, 1974, 1976). Zircon and glass are the important phases in this respect, although the use of zircon in some cases is thwarted by low abundance and fine-grain size. On the other hand, hydrated glass shards are typically the most abundant component of tephra beds and commonly the only datable phase present.

The glass-ITPFT technique was first applied in New Zealand to three widespread and stratigraphically important rhyolitic horizons from Wanganui Basin (Alloway et al., 1993). In that study, the glass-ITPFT ages, in conjunction with a revised magnetostratigraphy, demonstrated that the then existing Plio–Pleistocene marine chronology required significant age

Figure 10 Close correspondence between glass-DCFT and glass-ITPFT ages determined in University of Toronto FT Laboratory. Dashed line is 1:1 line. Regression line through data points has $r^2 = 0.989$.

FT ages determined at the University of Toronto FT Laboratory. Number in brackets indicates number of samples dated. All the glass-FT ages in this table are based on a calibration using $\lambda_D = 1.551 \times 10^{-10} \text{ year}^{-1}$, a zeta value of 318 ± 3 based on six irradiations at McMaster Nuclear Reactor, Hamilton, Ontario, the NIST SRM 612 glass dosimeter, and the Moldavite glass with an $^{40}\text{Ar}/^{39}\text{Ar}$ age of $15.21 \pm 0.15 \text{ Ma}$ (Staudacher et al., 1982). We now use a new calibration scheme that is based on a more precise $^{40}\text{Ar}/^{39}\text{Ar}$ age of $14.34 \pm 0.08 \text{ Ma}$ for the Moldavite glass (Laurenzi et al., 2003, 2007) giving a zeta value of 301 ± 3 . Mean age estimates using this new calibration are $\sim 5\%$ younger than the ages noted in this table – that is, within the error due to counting statistics for most of the Pleistocene tephra beds.

revision and confirmed that the previously published uncorrected glass ages were up to 50% too young (Figure 15). As discussed in Seward and Kohn (1997), the glass ages in Seward (1974, 1979) were determined before the effects of annealing on glass were fully recognized, and they demonstrate the extent to which annealing can lower uncorrected glass-FT ages. This revision had important implications for the evolution of

several other sedimentary basins in southern North Island that contained the same tephra beds.

Since that study, the technique has also been used to confirm the age of stratigraphically important rhyolitic horizons (i.e., Potaka Tephra, Shane, 1994; Rangitawa Tephra, Pillans et al., 1996; Waipuru and Vinegar Hill tephra, Naish et al., 1995; Ototoka Tephra, Alloway et al., 2004a), and has

Table 5 Comparison of glass-ITPFT ages for tephra beds in Wanganui Basin, New Zealand, with paleomagnetic and astronomically calibrated age estimates

Tephra	Glass-ITPFT age	Paleomagnetic age	Astronomical age
Kupe	0.63 ± 0.08	<0.78	0.65
Kaukatea	0.86 ± 0.08	0.78–0.99	0.9
Potaka	1.00 ± 0.03	0.99–1.07	0.99
Rewa	1.20 ± 0.14	ca. 1.19	1.19
Mangapipi	1.51 ± 0.16	1.19–1.77	1.54
Pakihikura	1.58 ± 0.08	1.19–1.77	1.60
Table Flat	1.71 ± 0.12	1.19–1.77	1.65
Vinegar Hill	1.75 ± 0.20	1.19–1.77	1.75
Waipur	1.79 ± 0.15	1.77–1.95	1.83

Data from Pillans et al. (2005). All ages in Ma with $\pm 1\sigma$.

Figure 11 Photomicrograph of zircons separated from a contaminated tephra bed. Primary zircons (arrowed) can be identified by glass adhering to them. Detrital zircons in this tephra are generally darker, more rounded, and lack glass mantles. Zircons are $\sim 150\text{-}\mu\text{m}$ long. Modified from Naeser CW, Briggs ND, Obradovich JD, and Izett GA (1981) *Geochronology of Quaternary tephra deposits*. In: Self S and Sparks RSJ (eds.) *NATO Advanced Studies Institute Series C. Tephra Studies*, pp. 13–47. Dordrecht: Reidel.

been pivotal in establishing a robust Plio–Pleistocene tephrostratigraphic framework throughout North Island, New Zealand (Alloway et al., 2004c; Naish et al., 1998; Pillans et al., 1994, 2005; Shane et al., 1996; Figure 14). More recently, ITPFT ages have been determined on glass shards from eight stratigraphically important macroscopic tephra layers from ODP-core 1124C (Alloway et al., 2005; Carter et al., 2004).

In a careful interlaboratory comparison, Seward and Kohn (1997) reported zircon FT ages for five of the tephra beds in Wanganui Basin, four of which (Pakihikura, Potaka, Vinegar Hill, and Rewa tephtras) are in good statistical agreement with previously determined glass-ITPFT ages. Two of the tephtras (Rewa and Mangapipi) contain two age populations of zircons,

Figure 12 Flow diagram of steps in the external detector method of dating minerals. Details of laboratory procedures are in Naeser (1976). Modified from Naeser CW, Briggs ND, Obradovich JD, and Izett GA (1981) *Geochronology of Quaternary tephra deposits*. In: Self S and Sparks RSJ (eds.) *NATO Advanced Studies Institute Series C. Tephra Studies*, pp. 13–47. Dordrecht: Reidel.

the older interpreted by Seward and Kohn (1997) as detrital contamination, and the younger interpreted as the eruption age. The disagreement in glass and zircon FT ages for the Mangapipi tephra remains to be resolved.

The glass-ITPFT technique is well suited to the dating of distal silicic tephra and has permitted a direct and detailed comparison of stratigraphic and chronologic data in a variety of sedimentary environments in New Zealand. Furthermore, the technique has significantly improved the cross-correlation between tephrochronology, paleomagnetic chronology, and $\delta^{18}\text{O}$ stratigraphy in marine cores.

Indonesia

Introduction

Indonesia is situated adjacent to the Sunda subduction system, which has produced a 1600-km-long volcanic arc with as many as 129 historically active volcanoes, extending from Sumatra in the northwest to Sulawesi in the southeast of the Indonesian

Figure 13 (a) Photomicrograph of crystal (left) and (b) image of the crystal in a muscovite detector (right). In the external detector method, spontaneous fission tracks are counted in the crystal (in this example, an apatite grain), and induced tracks are counted in the detector. Reproduced from Naeser CW and Naeser ND (1989) Laboratory procedures and techniques. In: Crowley KD, Naeser CW, and Naeser ND (eds.) *Geological Society of America Short Course Notes: Fission-Track Analysis: Theory and Applications*, pp. 3-1–3-17. Boulder, CO: Geological Society of America.

archipelago. Sumatra, in particular, contains a great variety and number of volcanoes. Many of these volcanoes are dormant but a few have erupted during historic time (i.e., Marapi and Singgalang–Tandikat). To date, much of the volcanological research conducted in Sumatra has focused on the eruptive history of Toba caldera (e.g., Chesner et al., 1991), and the best record of Indonesian arc volcanism is from tephra layers preserved in ODP-sedimentary cores retrieved from the north-eastern Indian Ocean adjacent to Sumatra (e.g., Dehn et al., 1991; Lee et al., 2004). Many of these tephra layers have yet to be correlated to their onshore eruptive source areas, confirming that there is little known about the eruptive history of many volcanic centers located in Sumatra. In Indonesia, the glass-FT dating technique has been applied to tephra erupted from Toba and Maninjau calderas, situated in northern and west-central Sumatra, respectively (Figure 16).

Toba

The Toba caldera complex consists of four overlapping calderas, the youngest of which is the world's largest caldera (100×30 km) and envelopes the three older calderas. An estimated $2500\text{--}3000$ km³ of dense-rock-equivalent pyroclastic material, termed the Youngest Toba Tephra (YTT), was erupted from the youngest caldera during one of the largest single volcanic eruptions in geological history (Rose and Chesner, 1987). Glass-FT ages for YTT have been determined from sites in Malaysia (68 ± 7 ka; Chesner et al., 1991) and distally in northwest India (84 ± 16 ka; Westgate et al., 1998) and are indistinguishable from an $^{40}\text{Ar}/^{39}\text{Ar}$ age of 73 ± 4 ka (Chesner et al., 1991) and K–Ar ages of 75 ± 12 ka (on biotite) and 74 ± 3 ka (on sanidine) (Ninkovitch et al., 1978). Certainly,

the very widespread distribution of YTT through southern southeast Asia and across the Indian Ocean makes it a very useful marker for dating archaeological sites on the Indian subcontinent (Westgate et al., 1998).

Maninjau

Maninjau is a volcanic edifice situated in the Padang Highlands ~ 300 km to the south of Toba in west-central Sumatra (Figure 16). The central part of this edifice is occupied by a collapsed caldera 20 km long and 8 km wide, and is now occupied by a lake with an estimated volume of 100 km³. The caldera lake parallels the Sumatran volcanic front and is located within the northwest–southeast trending Sumatran fault zone, which runs the entire length of Sumatra. Glass-FT and radiocarbon techniques were used by Alloway et al. (2004b) in an attempt to determine an accurate age for the Maninjau eruptive succession. Glass-ITPFT and -DCFT ages give a weighted mean of 50 ± 3 ka ($n=3$), and, together with concordant ^{14}C ages, give a timing for the latest silicic eruptive activity at 52 ± 3 ka, an age supported by the occurrence of an underlying silicic tephra bed that is geochemically indistinguishable from the ca. 75 ka YTT. This new age for the Maninjau eruptives is significantly different from previous and disparate FT (ca. 70–80 ka, Nishimura et al., 1978) and K–Ar (ca. 0.28 ka, Leo et al., 1980) determinations.

Concluding Statement

We have demonstrated that FT-dating methods applied to volcanic glass and zircon can produce accurate and precise

ages of Quaternary events in regions affected by Quaternary silicic volcanism. Although precision levels are inferior to those achieved by the $^{40}\text{Ar}/^{39}\text{Ar}$ method, FT methods are particularly useful for dating K-poor, calc-alkaline volcanics, and highly vitric tephra beds. Other favorable attributes include the small sample requirement for glass-FT ages and the grain-discrete methodologies used, which neutralize the contamination problem. Importantly, setting up a FT dating laboratory is a comparatively inexpensive operation because of its low-technology and low-maintenance requirements. Accordingly, it is very applicable to volcanic regions of the world where monetary resources are limited.

Introduction

Rivers are a dominant feature of most landscapes; therefore fluvial sediments are widespread. Fluvial deposits are represented by a continuum of sediment types that range from clay- to gravel-size particles, and include both terrigenous and organic deposits. Fluvial sediments provide an important link between weathering and slope processes in source areas as well as deltaic and coastal processes within depositional basins. Investigations of fluvial sediments are legion; recent syntheses include those by Miall (1996), Blum and Törnqvist (2000), and Bridge (2003). Two additional aspects of fluvial sediments deserve mention. First, these deposits represent economically important reservoirs of oil, natural gas, and water and, include significant coal reserves. Second, fluvial sediments provide critical records of past and present geologic processes and terrestrial environments. This article summarizes the major characteristics of fluvial sediments and discusses key differences between river systems of continental interiors and those associated with subsiding continental margins.

Fluvial Sediments

Fluvial sediments consist predominantly of channel and overbank deposits (Allen, 1965). Channel deposits are dominated by sand and gravel and represent the bed load of rivers. Overbank deposits generally consist primarily of clay, silt, and lesser amounts of very fine to fine sand and represent suspended-load sediments that accumulate on floodplains. Organic sediments such as peat, and chemical sediments such as carbonate and evaporite minerals, are also important constituents in some overbank settings.

Channel Deposits

Channel deposits consist of channel-bar and channel-fill sediments (Bridge, 2003). Channel deposits commonly occur as

isolated lenticular sand bodies (i.e., ribbon sands) or as thick sheet sands associated with channel belts (Figures 1–3). Channel belts are floodplain areas containing active and abandoned channels and channel bars that record the activity of individual channel systems.

Channel-bar deposits

Channel bars typically form in areas where decreasing flow velocities lead to bed-load sedimentation, such as along the inner bend of river meanders (Figure 4(a)). Channel-bar sediments are stratified sands and gravels, which are arranged in sets of large-scale inclined strata (Bridge, 2003; Figure 3). Large-scale inclined strata consist of gently dipping cross strata that reflect episodic migration of major bar forms (i.e., point bars, side bars) in response to channel translation and/or expansion (Figure 4(b)). The base of large-scale inclined strata sets is an erosional bounding surface, which often is overlain by rip-up clasts derived from fine-grained bed and bank materials. Within large-scale inclined strata, smaller-scale sets of cross-stratified sand and/or gravel are present (Figures 3 and 4(c)). These smaller-scale packages of cross-stratified deposits represent bed forms such as dunes and ripples that migrate along the surface of major bars and the bed of channels. Common sedimentary structures associated with these smaller bed forms include small- to medium-scale trough and planar cross-bedding as well as small-scale ripple stratification (Bridge, 2003). Finer-grained sediments such as mud can be present in the upper portion of bar deposits, or occur as mud drapes that separate sets of cross strata.

Channel-fill deposits

Channel-fill deposits are highly variable; sediments range from coarse-grained sand and gravel to fine-grained mud and organic sediments. Specific characteristics of channel fills depend on flow conditions at the time of channel abandonment. In vertical profiles through channel-fill deposits, grain size

Figure 1 Geologic map of the Mississippi River floodplain near Natchez, Mississippi. Four Holocene Mississippi River channel belts are shown. Modified from Aslan A and Autin WJ (1999) Evolution of the Holocene Mississippi River floodplain, Ferriday, Louisiana: Insights on the origin of fine-grained floodplains. *Journal of Sedimentary Research* 69: 800–815.

generally decreases upwards. Grain size also tends to decrease in a downstream direction. The dominance of coarser-grained bed-load deposits or finer-grained suspended-load sediments depends on whether or not the channel-fill succession represents an active or passive channel fill. Active fills are typically associated with upstream segments of abandoned channels where flow reduction was gradual. In contrast, passive fills are often associated with the central or lower portions of abandoned channels where flow reduction was severe. Active fills are characterized by bed-load deposits that represent the migration of bar forms and smaller-scale dunes and ripples within the upstream portion of the abandoned channel. As flow wanes, active channel-fill deposits transition upward to smaller grain sizes and thinner bed sets representing progressively smaller bars and bed forms. Passive fills are represented by clay, silt, and very fine sand deposited from suspension as well as organic sediment such as peat. These deposits are concentrated in the middle and downstream portions of an

abandoned channel and are associated with rapid decreases in flow such as occurs during neck cutoff and formation of an oxbow lake.

Overbank Deposits

Overbank sediments accumulate during floods in natural-levee, crevasse-splay, and flood-basin environments (Figure 5). Sediment grain size and accumulation rate decreases away from the active channel (Figure 6(a)). Avulsion, the abandonment of all or part of a channel belt in favor of a new course, also plays an important role in the accumulation of overbank deposits (Allen, 1965; Smith et al., 1989). In general, overbank sediments have received considerably less attention than channel deposits (Farrell, 1987). Modern examples of overbank deposits are numerous (Aslan and Autin, 1999; Farrell, 1987; Smith et al., 1989). Classifications of these deposits are presented in Platt and Keller (1992) and Miall (1996). Although

Figure 2 Satellite image of the Mississippi River floodplain south of Baton Rouge, Louisiana. Cultivated areas located adjacent to the river are on natural levees. Flow direction is to the southeast.

overbank deposits are sometimes viewed as monotonous successions of fine-grained alluvium, the recognition of paleosols in ancient overbank sediments has proved useful for subdividing and interpreting these deposits (Kraus, 1999). Additionally, there is increasing recognition that fine-grained sediments in both modern and ancient settings that have traditionally been interpreted as products of repeated overbank flooding, may represent episodes of avulsion (Kraus, 1999; Morozova and Smith, 1999; Slingerland and Smith, 2004; Smith et al., 1989; Stouthamer and Berendsen, 2000).

Natural-levee sediments

Natural levees are asymmetric ridges that slope away from active and abandoned channels toward adjacent flood basins. These features are typically well developed along low-gradient sinuous rivers with large suspended-sediment loads that are subject to deep overbank floods such as the Mississippi (Figure 2). Natural levees can rise up to 5 m above adjacent flood basins and are up to several kilometers wide on floodplains such as the Mississippi (Aslan and Autin, 1999; Törnqvist and Bridge, 2002).

Natural-levee sediments are wedges of sand and silt with minor amounts of clay that are typically thin and fine, away

Figure 3 Diagrams showing different scales of fluvial deposits. The upper diagrams show cross-sections through a channel belt composed of multiple depositional units. Large-scale inclined strata (individual examples shown by shaded portions of cross-sections) are the dominant depositional unit of the channel-belt deposits. At the smallest scale, cross strata representing migrating dunes are present within the large-scale inclined strata. from channel margins as a result of decelerating overbank flow (Figure 6(a)). Typical facies are similar to those of upper channel-bar deposits (Bridge, 2003), and consist of horizontal planar sand, small-scale cross-stratified sand, and bioturbated mud (Farrell, 1987). Proximal natural-levee deposits are relatively thick, sandy, and thick bedded. Distal natural-levee sediments are thinner, contain a greater percentage of silt and clay, and show more evidence of bioturbation and pedogenesis.

Natural-levee facies often occur as vertically stacked meter-thick, fining- or coarsening-upward sequences, which reflect periods of episodic overbank flooding and levee abandonment or progradation, respectively.

Crevasse-channel and crevasse-splay sediments

Crevasse channels are breaches in natural levees and transfer water and sediment from mainstem channels to flood basins. Crevasse channels often bifurcate into simple or complex distributary systems that discharge into flood-basin lakes or wetlands (Pérez-Arlucea and Smith, 1999; Smith and Pérez-Arlucea, 1994; Smith et al., 1989). The linear to lobate accumulation of sediment surrounding crevasse channels is referred to as a crevasse splay, and includes the distributary channel network (Figure 7(a)). Where crevasse channels flow into lakes, they form lacustrine deltas. Crevasse channels have natural levees as well as distributary- or terminal-mouth bars (Figure 7(b)). Crevasse-splay channels can extend up to 10 km into flood basins (Smith, 1986; Smith et al., 1989).

Crevasse-channel deposits are typically lenticular bodies of sandy channel-bar and sandy to muddy channel-fill sediments. Grain sizes associated with crevasse-channel deposits are similar to those of the bed-load fraction of the mainstem channel, and are somewhat coarser than other types of overbank sediments. However, muddy fine-grained crevasse-channel fills do occur (Pérez-Arlucea and Smith, 1999; Smith and Pérez-Arlucea, 1994). Stratification types include small- to medium-scale cross bedding and ripple lamination. Evidence of frequent changes in flow stage such as desiccation cracks and bioturbation features may be present (Bridge, 2003). Crevasse-channel deposit thicknesses will generally be smaller than the thickness of the main channel sand bodies.

Crevasse-splay deposits range from tabular to wedge-shaped packages of interbedded sand and silt with lesser amounts of mud. Individual crevasse-splay sand bodies are generally 1–2 m thick. Strata are commonly bioturbated and ripple laminated (Farrell, 1987). Individual splay packages often show upward-coarsening or upward-fining sequences similar to natural-levee deposits (Pérez-Arlucea and Smith, 1999). Upward-coarsening sequences reflect crevasse-splay progradation whereas deposition of overbank silt and clay during waning flood stages produces upward-fining deposits. Crevasse-splay deposits thin or thicken away from channel margins depending on local floodplain topography (Willis and Behrensmeier, 1994). Crevasse-splay sedimentation is

particularly important within avulsion belts (Smith et al., 1989) and is responsible for rapid fine-grained floodplain aggradation, a key attribute of avulsion.

Flood-basin sediments

Flood basins are broad seasonally flooded depressions that separate channel belts (Figure 8). These areas are characterized by low relief, shallow water tables, and complex drainage channel networks. In humid settings, flood basins are vegetated and contain lakes and perennial or seasonal wetlands. In more arid environments, flood basins are sparsely vegetated

and can have ephemeral lakes. Eolian processes may also be important in arid settings.

Flood-basin deposits are generally tabular accumulations of clay and silt that bury channel deposits or interfinger with sand bodies representing minor floodplain channels and crevasse-splay deposits (Aslan and Autin, 1999; Figures 9 and 10). Flood-basin sediments are often cross-cut by channel-belt sand bodies (Stouthamer and Berendsen, 2000). In Quaternary settings, these deposits are typically meters to tens of meters thick, but can be hundreds of meters thick in pre-Quaternary alluvial successions. Slow sediment accumulation

Figure 8 (a) Seasonal flooding of the Orinoco Delta, Venezuela. Vast tracts of interdistributary flood basins are inundated for several months of each year. During this time, only the crests of natural levees of distributary channels are subaerially exposed. (b) Mud cracks developed in flood-basin silt and clay during the dry season on the Orinoco Delta. This area is completely inundated during the rainy season.

rates in flood basins lead to soil development. Bioturbation features such as root mottles and burrows along with soil nodules and mud cracks are common in these deposits.

Flood-basin sediment characteristics largely depend on climatic conditions. In humid areas with a shallow fluctuating water table (i.e., seasonal wetlands), gray sediment colors and yellow-brown to red color mottles reflect episodes of seasonal wetting and drying. Authigenic minerals such as iron and manganese oxides, calcite, and gypsum can be common in these settings (Aslan and Autin, 1999). If smectitic clays are present, seasonal wetting and drying produces pedogenic slickensides and desiccation cracks. In more perennially saturated flood basins, elevated water levels and low clastic input leads to widespread peat accumulation (Flores, 1981). If clastic input is significant, bioturbated flood-basin sediments will often

interfinger with laminated lacustrine clay and silt. Lacustrine strata are concentrated in topographic depressions where water levels are perennially elevated and reducing conditions prevail. These deposits often contain reducing minerals such as pyrite, vivianite, and jarosite. In more arid settings, flood-basin sediments and playa-lake deposits contain a greater percentage of mud cracks, bioturbation features, and authigenic minerals such as calcite, gypsum, and other evaporite minerals.

Avulsion deposits

Avulsion is common in many low-gradient alluvial river systems and is best known from studies of the Rhine–Meuse delta, the Saskatchewan River, and the Mississippi River and Delta (Aslan et al., 2005; Smith et al., 1989; Stouthamer and Berendsen, 2000). A significant aspect of avulsion is that

Figure 10 (a) Map of Holocene floodplain deposits of the Mississippi River near Natchez, Mississippi. (b) Cross-section showing typical overbank sediments in the region. Brown silt and sand wedges represent natural-levee deposits. Gray sand and silt represent crevasse-splay sediments (thin sheets to lenticular bodies) whereas the thicker sand accumulations represent floodplain channels. Gray mottled mud and blue-gray massive mud represent flood-basin environments associated with predominantly oxidizing and reducing conditions, respectively. Dark gray laminated mud represents lacustrine strata. Reproduced from Aslan A and Autin WJ (1999) Evolution of the Holocene Mississippi River floodplain, Ferriday, Louisiana: Insights on the origin of fine-grained floodplains. *Journal of Sedimentary Research* 69: 800–815.

this process accounts for large volumes of fine-grained overbank sedimentation on floodplains (Aslan and Autin, 1999; Pérez-Arlucea and Smith, 1999; Smith et al., 1989). During an avulsion, water and sediment escape from the main channel and are transferred to the floodplain through a series of prograding crevasse-splay complexes and/or anastomosing channels (Smith et al., 1989). These channels deposit silt and clay and lesser amounts of sand in local floodplain depressions such as wetlands and lakes. As these topographic depressions fill

with sediment, the locus of floodplain deposition shifts down-valley. Because avulsive deposition occurs at all stages of flow and is not restricted to relatively rare large-magnitude floods, this process results in rapid floodplain aggradation. Texturally, avulsive deposits strongly resemble fine-grained sediments that are typically associated with overbank flooding. However, the stratigraphic architecture of avulsive deposits differs from that of typical overbank deposits (Figure 6(b)). Overbank flooding causes grain size and sediment accumulation rate to

Figure 11 (a) Traditional classification scheme for alluvial channels. decrease away from the active channel. In contrast, avulsion deposit grain sizes do not vary systematically as a function of distance from the active channel. In fact, sedimentation rates can actually increase away from the active channel.

Fluvial Channel Patterns

Fluvial channels have been traditionally subdivided into straight, meandering, and braided (Leopold and Wolman, 1957). More recent classifications recognize anastomosing channels (Miall, 1977, 1996; Rust, 1978; Figure 11(a)). These classifications emphasize two factors: channel sinuosity and bifurcation patterns. For example, braided rivers are characterized by channel bifurcation around bars or islands and low channel sinuosities, whereas anastomosing channels are separated by larger-scale flood basins (Bridge, 2003; Makaske, 2001; Schumm, 1977, 1985). Problems with existing channel classification schemes include measurements of the sinuosity of multichannel rivers, calculations of braiding indices, and delineation of individual channels versus channel belts. Additionally, channel patterns are not mutually exclusive. For example, anastomosing rivers can have braided channel segments (Bridge, 2003). Discrimination of channel patterns using channel characteristics and hydrologic data can be problematic and remains an area of continued research (Lewin and Brewer, 2001; Van den Berg and Bledsoe, 2003). An alternative alluvial river classification scheme proposed by Makaske (2001) subdivides channel systems based on numbers of channel belts, braiding characteristics, and channel sinuosity (Figure 11(b)). Although floodplain classification has received far less attention than channel classification, Nanson and Croke (1992) provide a recent classification of floodplain systems.

Changes in channel patterns are commonly associated with one or more of the following variables (1) discharge, (2) sediment load and type, (3) regional gradient, and (4) bed or

bank materials (Schumm, 1977; 1985). In general, increases in discharge, bed load, and gradient favor the development of low-sinuosity or braided streams. In contrast, decreases in discharge and gradient and increases in suspended-sediment load favor the development of meandering rivers or anastomosing systems. Anastomosing rivers are especially common where regional rates of aggradation are high and bank materials are cohesive (Makaske, 2001; Smith, 1986).

Sedimentary Records of Quaternary Fluvial Systems

Sedimentary records of Quaternary fluvial systems vary dramatically in terms of their abundance, alluvial architecture, and degree of stratigraphic completeness. These differences are demonstrated by comparing fluvial sediments from eroding continental interiors with those associated with subsiding continental margins.

Fluvial Records from Eroding Continental Interiors

Fluvial sediments of continental interiors typically reflect alternating episodes of aggradation, incision, and soil formation, and are located in river valleys. Fluvial sediments in these settings undergo extensive erosion and sediment reworking. Thus, they have a low preservation potential and provide incomplete or discontinuous records of fluvial activity. The erosional nature of fluvial records in continental interiors stems largely from long-term rock and surface uplift driven by erosional isostasy or tectonic processes, which leads to fluvial incision (Pederson et al., 2002). Shorter-term episodes of aggradation and incision associated with glacial-interglacial cycles are superimposed on this long-term uplift and incision. Collectively, these processes lead to the development of flights of down-stepping terraces along many major river valleys of continental interiors (Figure 12).

Figure 12 (a) River gravels associated with a Quaternary Gunnison River terrace near Grand Junction, Colorado. The terrace strath is cut into Cretaceous sandstone and is approximately 100 m above the modern Gunnison River. This terrace is part of a flight of down-stepping Quaternary terraces in the region, all of which are associated with abundant gravel. View is upstream. (b) Quaternary river gravels overlain by reddish overbank silty sand deposits of a Quaternary Colorado River terrace near Grand Junction, Colorado. The terrace strath is cut into Cretaceous shale and is approximately 30 m above the modern Colorado River. View is upstream.

Figure 13 (a) North Fork of the Gunnison River valley near Hotchkiss, Colorado. This river drains volcanic and sedimentary rocks of the central Rocky Mountains, and the channel and floodplain are represented by abundant gravel and sand. Flat benchlands in the background represent river terraces (arrows). View is upstream. (b) Cutbank along the Colorado River near Grand Junction, Colorado showing channel-bar gravel overlain by overbank silt and sand.

Sand and gravel are common constituents of fluvial sediments in continental interiors, and are associated with channel bars and bed-load deposition (**Figure 13(a)**). Overbank sediments are often represented by thin veneers (**Figure 13(b)**). The predominance of coarse-grained sediment reflects the relatively steep slopes of rivers in these settings and low floodplain relief, which combine to inhibit the deposition and preservation of silt and clay. The relative paucity of overbank silt and clay in continental interiors has led some workers to suggest that overbank flooding plays a minor role in the development of floodplains in these settings (**Wolman and Leopold, 1957**).

Fluvial sediments of continental interiors (e.g., Holocene arroyo fills) are often associated with complex alluvial stratigraphies that reflect alternating episodes of aggradation, entrenchment, and soil formation (**Figure 14**). Alluvial successions in the southern Great Plains of the United States provide excellent examples of complex fill histories, and contain regionally correlative stratigraphic units. For example, numerous Holocene valley-fill deposits in this region record aggradation from 5 to 2 ka, soil formation from 2 to 1 ka, and

entrenchment since 1 ka followed by episodic floodplain sedimentation (**Figure 14(b)**). The correlative nature of the alluvial stratigraphic units in these valleys, and similarities in the timing of the major aggradation and incision events suggest that climatic influences and changes in river hydrology have largely controlled the alluvial stratigraphy of the southern Great Plains (**Hall, 1990**) as well as elsewhere in the southwestern United States (**Walters and Haynes, 2001**). Narrow valley widths relative to channel widths cause rivers to rapidly rework older alluvial deposits in these settings. Thus, the length of time represented by the fluvial sediments is limited.

Fluvial Records from Subsiding Continental Margins

Fluvial sediments of continental margins typically accumulate in subsiding sedimentary basins. For example, the Gulf Coast region of the United States represents a subsiding passive margin that consists of stacked successions of fluvial-deltaic Quaternary units (**Figure 15**). Because these sediments are accumulating in a subsiding basin, they have a high preservation potential and the sedimentary records of fluvial activity

Figure 14 (a) Map showing locations of alluvial rivers that have undergone Holocene filling and entrenchment. BC, Brushy Creek; CC, Carnegie Canyon; CL, Candy Lake; CR, Colorado River; DC, Delaware Canyon; DM, Double Mountain Fork; HC, Hog Creek; EF, Elm Fork of the Trinity River; KL, Keystone Lake; LC, Little Caney River; MC, McGee Creek; NF, North Fork of San Gabriel River; PR, Pedernales River; RC, Richland Creek; SS, South Sulfur Spring. (b) Cross sections showing the Holocene alluvial stratigraphy at three locations in (a). Sand and gravel deposition and Holocene aggradation commenced ~5 ka in all three locations, which produced depositional unit 'B' in the cross sections. From 2 to 1 ka, sedimentation slowed and a cumelic, organic-rich soil (Copan Soil) developed. At 1 ka, channel trenching occurred throughout the southern Great Plains. Channel trenching was followed by episodic floodplain sedimentation, which produced depositional unit 'A' in the cross sections. Ages are in radiocarbon years before present. Premiddle Holocene sediments (depositional unit 'C') are rare in the valley fills. These types of valley-fill fluvial deposits have low long-term preservation potential because of the narrow valley widths and the frequency of channel entrenchment and filling. Reproduced from Hall SA (1990) Channel trenching and climatic change in the southern U.S. Great Plains. *Geology* 18: 342–345.

are more complete than those of continental interiors. Rivers in this region occupy broad alluvial valleys separated by low upland divides. Large floodplain widths relative to channel widths, gentle slopes, and depositional relief created by sedimentation along channels (i.e., elevated alluvial ridges) lead to the accumulation and preservation of significant volumes of fine-grained overbank deposits, in addition to coarse-grained channel sediments (Figure 16).

Late Quaternary fluvial sediments of continental margins predominantly occur as valley-fill complexes associated with glacial–interglacial cycles (spans ~100 ka; Figure 17). Packages of fluvial sediments accumulate in response to changes in sea level and river hydrology that reflect glacial versus interglacial conditions (Blum and Törnqvist, 2000). In the example of the Colorado River of the Texas Gulf Coast region, the river incised and filled its current valley over the past 70 ka (Blum and Price, 1998). The valley fill consists of a basal late Pleistocene sand-dominated unit that is overlain by a mixed sand- and mud-rich succession of Holocene age. The basal sand-dominated unit comprises a series of down-stepping terraces and well-expressed buried soils (Figure 17). During the Holocene, the valley filled with fine-grained

muddy overbank deposits that encase channel and minor overbank sand bodies. Similar muddy overbank sediments are thin or absent from the basal late Pleistocene portion of the valley fill. This major difference in the abundance of overbank sediments in Holocene and late Pleistocene portion of the valley fill could reflect less frequent episodes of deep overbank flooding during the late Pleistocene (Blum and Törnqvist, 2000).

Over longer time scales involving multiple glacial–interglacial cycles, avulsion during late stages of valley filling can lead to abandonment of an alluvial valley (Blum and Törnqvist, 2000). Avulsion causes a shift in the location of the valley axis and future valley incision and filling, which causes the ages of valley-fill complexes to vary both laterally and vertically (Figure 18). In areas of active subsidence, alluvial valley-fill complexes locally onlap and cross cut one another. The basal valley-fill unconformities form a composite unconformity that is overlain predominantly by sandy channel-belt deposits with well expressed paleosols. In contrast, the upper portions of the valley fills are a combination of fine-grained overbank and sandy channel deposits.

Figure 15 Geologic map of the Texas Gulf Coastal Plain showing the distribution of late Quaternary deposits and major river valleys. Summary

Fluvial sediments provide important records of terrestrial environments that are critical for interpreting geologic histories of continental settings. These sediments are also important for evaluating petroleum, coal, and water resources. Fluvial sediments are traditionally subdivided into coarse-grained channel deposits and fine-grained overbank sediments. Channel deposits consist of channel-bar and channel-fill sediments, and accumulate in response to downstream progradation of large-scale bar forms and periodic channel abandonment. Overbank deposits accumulate in natural-levee, crevasse-splay, and flood-basin environments through a combination of overbank flooding and avulsion. Fluvial sediments vary in terms of abundance, architecture, and stratigraphic completeness between continental interiors and margins. In eroding continental interiors, fluvial sediments are represented by flights of terraces underlain by coarse-grained deposits. Fine-grained overbank sediments are relatively rare. These fluvial sediments reflect long-term incision and common sediment reworking, and thus, they preserve relatively incomplete records of fluvial activity. In subsiding continental margins, thick accumulations of both sandy channel and muddy overbank deposits are preserved. These thick fluvial successions provide relatively complete long-term records of fluvial activity.

Responses to Rapid Environmental Change

This article is reproduced from the previous edition, Volume 1, pp. 686–694, © 2007, Elsevier B.V.

Introduction

The recognition of centennial to millennial scale environmental change, notably abrupt climate change, has sparked a great interest in how such rapidly changing boundary conditions influence landscape processes. Rivers are widely considered geomorphic entities that are highly sensitive to environmental change, but it is increasingly being recognized that the fluvial response is extremely complex, with considerable spatiotemporal variability (Knox, 1983). This article provides an overview of the variety of fluvial responses to rapid environmental change and is intimately linked to the preceding article that focuses on longer-term (glacial–interglacial scale) fluvial responses. Primarily, the article will discuss the effects of rapid climate change on fluvial systems in the alluvial reach (i.e., that portion of the fluvial system that is most likely to preserve – at least in a temporary fashion – a stratigraphic record); bedrock rivers are discussed in more detail elsewhere. The first part consists of a discussion of general concepts and criteria for the recognition of fluvial responses, followed by a selection of case studies that provide examples of the different manifestations of late Quaternary fluvial responses to rapid environmental change.

General Concepts

It is usual to distinguish between climate change, base-level (commonly sea-level) change, and tectonism as the three categories of external (or allogenic) forcing of fluvial systems. In addition, a distinction has been made between upstream and downstream controls. While climate change is typically an upstream control (i.e., the forcing propagates downstream through the drainage basin), sea-level change provides a distinct downstream control and can only affect the lowermost reaches of the fluvial system. Considerable debate has centered on the question of how far upstream sea-level control can propagate and it is likely that this varies greatly, depending on variables such as slope and sediment supply (Blum and Törnqvist, 2000). In principle, tectonism can affect any segment of the fluvial system. In addition, the various allogenic controls commonly operate simultaneously.

Modes of Response to Allogenic Forcing

There are different mechanisms of fluvial response to allogenic forcing:

1. changes in the discharge regime;
2. changes in channel pattern (fluvial style); and
3. changes in the longitudinal profile by means of aggradation or degradation (incision).

Perhaps the most obvious and direct response to climate forcing is the change of discharge regime and associated changes in hydraulic geometry parameters, such as channel width, depth, and sinuosity. Such adjustments may in some cases lead to full transformations of fluvial style.

Changes in fluvial style have been the subject of research for a long time, commonly focusing on the time period around the Pleistocene–Holocene transition (Kozarski, 1983; and numerous others). Many of these investigations concern the transformation from braided to meandering channel patterns. While there is a lively ongoing debate on the boundary conditions that cause rivers to braid or meander (Lewin and Brewer, 2001; Van den Berg, 1995), it appears likely that braiding is favored by a high bed load and a high stream power (i.e., discharge and valley slope). In addition, several other factors have been mentioned in the literature (e.g., limited bank stability). Rapid climate change can modify boundary conditions that control fluvial style, but changes in fluvial style due to climate forcing can be spatially nonuniform.

Perhaps the most prolific response of the fluvial system to allogenic forcing is the adjustment of the longitudinal profile, either by aggradation or by degradation (incision). The concept of grade (Mackin, 1948) postulates that alluvial rivers strive to attain an equilibrium profile characterized by a more or less balanced sediment budget, typical of stable boundary conditions in terms of base level, discharge, and sediment supply. Disruptions of this delicate balance commonly occur by means of changes in the proportion between water discharge (Q_w) and sediment supply (Q_s). It is important to note that sediment supply in this context refers strictly to bed load, given the fact that rivers are virtually never saturated with respect to the transport of suspended load, while the supply of bed load at times exceeds sediment-transport capacity. Figure 1 shows how the balance between Q_w and Q_s dictates whether a fluvial reach will incise, aggrade, or maintain equilibrium. In this context, it is important to reiterate that disruptions in the Q_w/Q_s ratio may be accommodated by other adjustments (such as sinuosity), rather than by lowering or raising the longitudinal profile.

Recognizing Fluvial Incision

Fluvial aggradation and incision not only reflect changes in the sediment budget but also leave the most tangible imprint in the stratigraphic record. In fact, many studies of fluvial archives aim to identify fluvial unconformities resulting from phases of incision with regional significance that may be ascribed to allogenic forcing. However, the proper recognition of regional unconformities representing widespread incision has proven challenging for a number of reasons. This is due to the simple fact that river channels are erosional features by definition. Following Salter (1993) and Best and Ashworth (1997), it is

Figure 1 Balance model for aggradation and degradation (incision) in alluvial rivers, as dictated by the relative proportion of water discharge and sediment supply, referred to by Bull (1991) as the balance between stream power and resisting power. Channels aggrade when sediment supply (bed load: amount and grain size) exceeds sediment-transport capacity as determined primarily by discharge and slope, and incise when the reverse is the case. The role of base-level change can also be inferred from this conceptualization. Base-level rise tends to reduce the slope and therefore promote aggradation, whereas base-level fall may increase the slope leading to incision (also depending on the morphology of the surface that is exposed). Originated from an unpublished diagram by W. Borland. Reprinted from Bull WB (1991) *Geomorphic Responses to Climatic Change*. New York: Oxford University Press, with permission from Oxford University Press.

therefore critical that distinction be made between fluvial scour, the autogenic (intrinsic) process that characterizes any alluvial channel (Figure 2) versus allogenic incision. Best and Ashworth (1997), working in the vertically aggrading Ganges–Brahmaputra Delta, showed that channel scour can lead to reworking of the channel belt to depths as much as five times the mean channel depth. They go on to show how the resulting stratigraphic phenomena can easily be mistaken for fluvial incision with regional significance. In fact, numerous examples can be gleaned from the literature where channel scour in overall aggradational settings may have been misinterpreted as fluvial incision.

So how can fluvial incision and aggradation be recognized in the stratigraphic record? Given the discussion above, this is a critical, yet by no means a trivial question. Distinction should be made as to whether incision/aggradation is measured relative to the channel bed or the floodplain surface. Incision of the channel bed can be the result of base-level change, vertical crustal movements, or changes in Q_w relative to Q_s (Figure 3(a)). However, changes in the discharge regime alone (i.e., the ‘flashiness’ of discharge) can cause floodplain aggradation or degradation, without vertical changes in the channel bed. Floodplains that are frequently inundated by deep overbank floods have the potential to aggrade to levels well above the channel bed (Figure 3(b)). If lateral channel migration goes along with a reduction of the peak discharge (e.g., as a result of a decrease in the frequency of major storms) a new floodplain will, over time, be established at a lower level, leaving the previous floodplain behind as a terrace.

These two mechanisms of fluvial terrace formation are shown schematically in Figure 4(a) and 4(b), respectively, and are further illustrated by means of animations available from the supplementary materials. Given these different mechanisms of terrace formation, a variety of combinations of processes are capable of producing – at least in theory – a plethora of stratigraphic results that may prove challenging to unravel (Blum and Törnqvist, 2000). For example, it cannot be ruled out that different allogenic forcings operate simultaneously and cause opposite stratigraphic results (Figure 4(c)). In this hypothetical example, floodplain aggradation due to an increase in peak discharge would occur simultaneously with channel-bed incision, for instance due to a slight base-level drop, and vice versa. Finally, it should be stressed that incision as defined here is broadly defined so as to encompass floodplain degradation in the absence of channel-bed incision. Obviously, long-term incision over vertical intervals that substantially exceed mean channel depth cannot occur without channel-bed incision.

The overarching conclusion is that inferring fluvial incision and aggradation from the stratigraphic record can be most successfully done when data are available on both floodplain surfaces and channel bases. Unfortunately, this presents the problem that in the naturally incomplete stratigraphic record channel bases tend to have a much higher preservation potential than floodplain surfaces. Therefore, it is absolutely critical that the criteria for recognition of fluvial incision and aggradation be explicitly discussed. Unfortunately, often this is not the case, and the literature is riddled with examples of studies

Figure 2 (a) Channel scour and fill in alluvial rivers leads to continuous reworking and deepening of the channel belt, exceeding mean bankfull channel depth. Modified from Salter T (1993) Fluvial scour and incision: Models for their influence on the development of realistic reservoir geometries. In: North CP and Prosser DJ (eds.) *Characterization of Fluvial and Aeolian Reservoirs: Geological Society Special Publication*, vol. 73, pp. 33–51. (b) Repeated bathymetric surveys of the Ganges–Brahmaputra confluence show the dynamic nature of alluvial channels and their capability to form scour holes about five times the average channel depth that are likely to rework channel belts over annual to decadal timescales. Reproduced from Best JL and Ashworth PJ (1997) Scour in large braided rivers and the recognition of sequence stratigraphic boundaries. *Nature* 387: 275–277. Caution must be taken not to confuse such phenomena with fluvial incision and associated floodplain degradation. Reprinted by permission from Macmillan Publishers Ltd.

that infer longitudinal-profile adjustments while potentially misinterpreting autogenic scour phenomena as reflecting regional incision (e.g., due to a focus exclusively on channel-belt bases rather than floodplain surfaces).

Complex Response and Response Time

A potentially large obstacle in the interpretation of fluvial stratigraphic records is the possibility of the occurrence of nonlinear responses. An experimental study by Schumm and Parker (1973) showed how a simple, rapid drop in base level can lead to alternating fluvial incision and aggradation.

Figure 3 (a) The Sabarmati River, Gujarat, India, about 100 km upstream from Ahmadabad, bordered by a ~40-m-high terrace. The uppermost terrace deposits date to ~12 ka, whereas the bars are ~4.5 ka in age (Srivastava et al., 2001), indicating spectacular incision that has been attributed to the early Holocene increase in monsoon activity that affected large sections of South Asia during this time (Tandon et al., 2006). Photograph courtesy Martin Gibling. Reprinted by permission from SEPM (Society for Sedimentary Geology). (b) The Amite River in southeast Louisiana after a peak discharge event. Note the high-water mark recognizable by the mud-covered vegetation. The lower arrow shows the approximate thickness of fine-grained overbank deposits overlying sandy point-bar strata. The upper arrow indicates the minimal amount of continued floodplain aggradation that can be expected if the current discharge regime remains unaltered.

The concept of ‘complex response’ was subsequently discussed at length by Schumm (1977), who advocated that such non-linearity can be caused by a variety of perturbations (sediment supply, tectonism), both upstream and downstream. The cyclic nature of the Schumm and Parker (1973) experiment was later substantiated by mathematical modeling (Slingerland and Snow, 1988).

Regardless of the possibility of complex response, it has long been recognized that fluvial responses to environmental forcing exhibit time lags of variable duration. For example, Bull (1991) defines the geomorphic response time as the sum of the reaction time (time between the perturbation and the initial adjustment) and the relaxation time (time between the initial adjustment and renewed equilibrium). The spirit of these concepts is not unlike the theoretical work by Paola et al. (1992), who introduced the concept of equilibrium time (T_{eq}), defined as

Figure 4 Hypothetical cross-sections illustrating contrasting mechanisms of fluvial incision, floodplain abandonment, and terrace formation (Blum and Törnqvist, 2000). (a) Equilibrium floodplain with lateral migration (from left to right) and minimal vertical aggradation, followed by a short phase of incision characterized by degradation of both the channel bed and the floodplain and a subsequent return to equilibrium conditions. This could be the result of either a reduction in bed load relative to discharge, a drop in base level, or tectonic uplift (or combinations thereof). (b) Fluvial system characterized by lateral migration and vertical aggradation of the floodplain due to frequent overbank flooding. A phase of floodplain degradation due to a reduction in peak discharge is followed by continued conditions of lateral migration and floodplain aggradation at a lower level. Note that the channel bed remains unchanged and that terrace formation is entirely the result of a drastic decrease in peak discharge and resulting floodplain degradation. (c) A combination of the processes operating in the previous two scenarios, where channel-bed degradation occurs simultaneously with floodplain aggradation due to increased overbank flooding. Subsequently, channel-bed aggradation coincides with reduced overbank flooding, resulting in the counterintuitive situation of simultaneous terrace formation and channel-bed aggradation.

$$T_{eq} = L^2/v$$

where L is the basin (river) length (a proxy for the size of the drainage basin) and v is the diffusivity (efficiency of sediment transport). It follows that small drainage basins that permit rapid sediment transfer are more likely to record abrupt, short-term climate changes than large fluvial systems. Recently, [Castelltort and Van Den Driessche \(2003\)](#) have applied this theory to 93 large rivers worldwide, suggesting that tens to hundreds of thousands of years are needed to fully accommodate changes in sediment supply and restore equilibrium conditions. In addition, these authors suggest that upstream forcing is in many cases accommodated in the fluvial transfer zone, implying that perturbations would not propagate to the river mouth. Nevertheless, as will be exemplified below, several cases have been documented of fairly rapid fluvial responses to

environmental forcing, including examples from large drainage basins.

Case Studies

This article focuses on climate controls, because sea-level fluctuations that affect the downstream portions of the longitudinal profile commonly act over longer time intervals. With the exception of episodic seismic events, tectonism also concerns longer timescales. The last glacial and its transition into the Holocene have witnessed numerous abrupt climate changes that have affected considerable parts of the globe. These changes manifest themselves as drastic fluctuations in temperature and precipitation, particularly well documented in the Greenland ice-core records. The Dansgaard–Oeschger events serve as some of the most prolific examples that were of specific importance in the North Atlantic region, but lower latitudes have experienced variations in monsoonal activity as well as higher frequency changes such as the El Niño–Southern Oscillation. In addition, solar forcing has been proposed as another mechanism for short-term climate change.

In many respects, the Pleistocene–Holocene transition can be viewed as one of the most abrupt climate changes of the last glacial–interglacial cycle, in essence corresponding to Termination I. This is particularly the case in temperate regions of the Northern Hemisphere that were strongly influenced, either directly or indirectly, by glaciation. These are also the environments that have the longest tradition of studies of late Quaternary fluvial evolution, so the discussion below will open with a brief overview of some of those findings. The subsequent sections present selected examples of fluvial responses to climate forcing over different timescales, with a premier emphasis on longitudinal-profile adjustments. It should be noted that the subdivision of examples reflects interpretations of the stratigraphic record by the respective authors, based on a variety of observational data. The examples range from monsoonal fluctuations that operate over 10^3 – 10^4 year timescales, to Dansgaard–Oeschger style abrupt (10^2 – 10^3 years) climate changes that have been particularly prominent in the North Atlantic region, as well as higher frequency and lower amplitude (10^0 – 10^3 years) climate fluctuations with variable causes that characterize the Holocene. The examples provided here not only concern different timescales but also contrasting environmental settings, ranging from the tropics to temperate regions (with the latter predominantly subarctic during the last glacial).

Pleistocene–Holocene Transition

A long tradition exists of studies of fluvial channel-pattern changes across the last glacial to interglacial transition, particularly in temperate regions outside of the former centers of glaciation. Such investigations have been numerous in the northwest European lowlands that experienced an overall transformation from periglacial conditions with sparse vegetation cover to temperate, deciduous forests with climate conditions roughly comparable to those of the present. For example, detailed mapping by [Berendsen and Stouthamer \(2001\)](#) of the floodplains and adjacent terraces of the lower Rhine and

Figure 5 Channel patterns along the Rhine and Meuse Rivers during the late Pleistocene and Holocene near the Dutch–German border. Note the braided channel patterns on the Weichselian (late Pleistocene) terraces, as opposed to the meandering Holocene fluvial style. Reproduced from Berendsen HJA and Stouthamer E (2001) *Palaeogeographic Development of the Rhine–Meuse Delta, The Netherlands*. Assen: Koninklijke Van Gorcum.

Meuse Rivers near the Dutch–German border (**Figure 5**) shows that braided channel patterns dominated during the last glacial, rapidly giving way to meandering planforms in the Holocene. Numerous investigators have argued that braiding was promoted by a high supply of bed load due to a lack of vegetation cover and active periglacial hillslope processes. In contrast, increased stabilization of soils and riverbanks by vegetation during the Holocene favored the transition to meandering patterns. These findings have been mostly substantiated by recent modeling (Bogaart et al., 2003a).

It is interesting to note that strikingly similar changes in fluvial style have been mapped along the Rhine and Meuse (**Figure 5**), despite the different character of these two rivers around the Pleistocene–Holocene transition, with the Rhine – unlike the Meuse – draining a substantially glaciated hinterland. Similar observations have been made in North America, with braided channel patterns dominating both glaciated drainage basins such as the Mississippi River (Fisk, 1944; Saucier, 1994) and ice-free settings along the Atlantic Coastal Plain (Leigh et al., 2004) during the last glacial. As will be discussed in more detail below, higher frequency changes in fluvial style and longitudinal-profile adjustments occurred during the Pleistocene–Holocene transition in northwest Europe.

Monsoonal Forcing

Precession-dominated fluctuations in monsoonal activity in low-latitude regions are well documented. A number of recent studies highlight the associated dramatic responses of fluvial systems over millennial or slightly longer timescales, including extensive work in the Himalayan Foreland Basin. Tandon et al. (2006) present a large body of data from the drainage basin of the Ganges River, suggesting that widespread fluvial incision (commonly on the order of tens of meters), floodplain

abandonment, and terrace formation was especially prominent during time intervals with a strengthened monsoon, particularly the period from about 15 to 5 ka. Similar processes operated farther west in India (**Figure 3(a)**). The preceding period around the Last Glacial Maximum, when the southwestern monsoon was suppressed and discharge was substantially lower, was characterized predominantly by fluvial aggradation. Goodbred (2003) pointed out similar relationships and demonstrated the intimate connection between accelerated incision in the drainage basin of the Ganges River during the hypsithermal (notably the early Holocene) and accelerated sedimentation rates in the Ganges–Brahmaputra Delta. The significance of this finding is that this giant sediment-dispersal system was capable of transmitting a climate signal over a very short (millennial) timescale, from source to sink. Studies like the ones discussed here have been possible because of rapid advances in optically stimulated luminescence dating and its application to strata that previously lacked robust age control.

Dansgaard–Oeschger Style Forcing

The North Atlantic region could be viewed as the type area for abrupt climate change, particularly during the last glacial. The Dansgaard–Oeschger events, characterized by sudden warming that lasted for no more than a few thousand years before reversing back to glacial conditions, are likely to have caused major landscape changes. By far the best-documented Dansgaard–Oeschger event is the most recent one (Bølling–Allerød–Younger Dryas), constituting the final episode of the last glacial. Numerous studies of northwest European rivers have revealed at least some commonality in changes of fluvial styles and terracing during this time interval. The Meuse River in The Netherlands has been particularly extensively studied (Huisink, 1997; Tebbens et al., 1999). Although these two

investigations use conflicting age models they share a number of findings, including a rapid (Tebbens et al., 1999) or gradual (Huisink, 1997) transition from full-glacial braided channel patterns to a meandering fluvial style during the Allerød, reversing back to braiding during the Younger Dryas. In addition, several phases of incision and aggradation have been inferred, although some of these have been subsequently questioned by Bogaart et al. (2003b) who drew the attention to the same 'scour versus incision' problem as discussed above. Nevertheless, Bogaart et al. (2003b), using a novel modeling approach aimed explicitly at understanding centennial to millennial scale climatic forcing of fluvial systems, show the plausibility of short-lived incision associated with abrupt climate change, comparable to the pioneering work by Knox (1972) that is discussed below. This finding is consistent with floodplain degradation at the Allerød–Younger Dryas transition along the Meuse, as inferred by Huisink (1997).

One intriguing challenge in studies of fluvial evolution is the possible impact of the numerous earlier Dansgaard–Oeschger events of the last glacial. Studies of fluvial successions from this time interval in The Netherlands (Van Huissteden and Kasse, 2001) have suggested that prior to the last Dansgaard–Oeschger event discussed above, fluvial systems exhibited mostly autogenic behavior with only few episodes of more widespread erosion. They point out that the nature of fluvial responses is dependent on overall environmental boundary conditions, with a particularly prominent role for vegetation and permafrost. Only during the final episode of the last glacial an alternation between open shrub tundra and woodland allowed more dramatic fluvial responses due to the vegetational control on the hydrologic cycle. Nevertheless, there is ample room for more studies of fluvial records of the last glacial, especially in light of the current feasibility of better chronological frameworks.

Holocene Climate Forcing

The potentially nonlinear nature of fluvial response to abrupt environmental change was discussed by Knox (1972), who argued that high-order tributaries in southwest Wisconsin located near a major ecotone responded in a highly sensitive way to Holocene shifts in atmospheric circulation. An abrupt transformation from prairie to hardwood forest ~6000 ¹⁴C years BP was associated with rapid alluviation along these streams. As shown in Figure 6, changes in fluvial activity are particularly concentrated in the relatively short interval following an abrupt shift in climate, largely due to the time lag in vegetational response. More specifically, a transition from arid to humid conditions provides a small time window with increased discharge and sparse vegetation cover, allowing accelerated hillslope erosion due to a limited infiltration capacity. This results in increased sediment yield and 'geomorphic work.' Knox (1972) raises the point that the exact nature of the fluvial response, in terms of incision versus aggradation, is highly dependent on location within the drainage network.

Somewhat different conditions prevailed in environments that are characterized by more flashy discharge regimes, with peak discharges as much as two or three orders of magnitude higher than mean annual discharge. This is illustrated by a number of rivers in central Texas, including the Colorado

Figure 6 Conceptual model of nonlinear fluvial response to climate forcing. Note that this model is intended to apply specifically to mid-latitude regions with an annual precipitation of 250–1500 mm. Also note that 'geomorphic work' could refer to both incision and aggradation, depending on location within the drainage basin. Reproduced from Knox JC (1972) Valley alluviation in southwestern Wisconsin. *Annals of the Association of American Geographers* 62: 401–410.

River (Blum et al., 1994). Figure 7 shows a cross-section of this fluvial system featuring three Holocene allostratigraphic units. While the base of each unit is found at a roughly constant level, their surfaces vary widely, with the early Holocene unit entirely draped by younger strata. Blum et al. (1994) explain this by variations in the persistence of deep flooding, which was especially prolific during the relatively humid time period 2500–1000 ¹⁴C years BP. In contrast, the past millennium was drier and led to the establishment of an inset floodplain at a lower level, along with pedogenesis and terrace formation.

Daniels and Knox (2005) provide an excellent example of a study of century-scale fluvial response, in their case with respect to the drought that characterized the interior of North America during the Medieval Warm Period. They show that tributaries in a small drainage basin in southwest Nebraska incised rapidly around 800–1100 ¹⁴C years BP, roughly synchronous to rivers elsewhere in Nebraska and Kansas. Drought in this semiarid region is associated with dramatic reductions in vegetation cover and a more variable discharge regime with less frequent, yet more powerful, floods. This would enable high erosion rates and the establishment of new floodplain levels several meters lower, within a time period of a few centuries or less. It appears that fluvial incision in this environment is correlated with drought, whereas in examples given

Figure 7 Three Holocene allostratigraphic units along the upper Colorado River, central Texas. For explanation see text. Reproduced from Blum MD, Toomey III RS, and Valastro S Jr. (1994) Fluvial response to Late Quaternary climatic and environmental change, Edwards Plateau, Texas. *Palaeogeography, Palaeoclimatology, Palaeoecology* 108: 1–21.

above, such as the Meuse River, early Holocene incision was associated with an increase in discharge (Bogaart et al., 2003b). This testifies again to the complexity of the fluvial response and its strong dependence on regionally specific boundary conditions.

Relatively rare are stratigraphic studies that focus on the response of the fluvial sediment transfer system to annual to decadal scale climate forcing. Naturally, it is most practical to study such relationships in the most recent sedimentary records, given the need for exceptionally high temporal resolution. Only a few environments remain that have been essentially unaffected by human intervention over the past decades or century. Recent work in the pristine foreland basin of the Amazon drainage (Aalto et al., 2003) suggests that floodplain aggradation is not a gradual process, but rather consists of rapid pulses of sedimentation separated by multiyear intervals of quiescence. These authors documented a strong correlation with the El Niño–Southern Oscillation, with rapid aggradation in the southern part of the Amazon Basin occurring during rainy La Niña intervals.

Summary

The interest in fluvial responses to rapidly changing climatic boundary conditions is here to stay, and will likely increase given the concerns about the impact of future global change. While there exists a rich literature of investigations of fluvial records for the past ~20 ka, studies over shorter (decadal or centennial) timescales are less common (Blum and Törnqvist, 2000). One likely reason for this is the formidable task of developing high-resolution geochronological frameworks in fluvial successions, environments that commonly pose serious challenges for numerical dating.

The diverse collection of examples presented herein shows that there is a wide variety of fluvial responses to climate forcing. For example, the impact of increased aridity or humidity can be opposite in different geographic regions, to a large extent depending on initial boundary conditions. As a result, the scientific literature on the topic covered by this article is somewhat overwhelming and confusing, with numerous

conflicting data and interpretations. To a considerable extent these conflicts are probably real, reflecting spatial variability, differences in sensitivity, and contrasting response times. However, it is likely that some of these conflicts simply stem from erroneous stratigraphic interpretations.

There are also discrepancies between field evidence and theory, given that large rivers may respond swiftly to environmental forcing, as so eloquently illustrated by the Ganges system. Thus, major challenges lie ahead. The emergence of better and more rigorous concepts that are more strongly rooted in theory, as well as better analytical tools (notably dating methods), will likely offer new opportunities to tackle these important issues.

Introduction

Fluvial terraces are important chronicles of (1) climatically driven changes in sediment supply, discharge, or base level that result in channel incision or aggradation, and (2) tectonically driven long-term uplift that results in channel incision and warping or faulting of terrace surfaces. A fluvial terrace, a relatively flat bench occurring along and above a river, is an abandoned floodplain surface that is separated from the modern floodplain (or a lower river terrace) by a steep slope, known as the terrace riser. River valleys often contain flights of multiple terraces that reflect long periods of terrace formation, a history that can be unraveled through mapping, surveying, and dating of fluvial terraces. As such, terraces are useful in studies of Quaternary climate change and the effects of climate change on landscape processes, such as increased upland erosion and the consequent increased sediment supply. In tectonic studies, terraces are useful for assessing both the rate of rock uplift at a given reach and differential rates of deformation along river valleys.

The causes and processes of terrace formation are briefly summarized and then case studies of terraces in Asia, New Zealand, and North America are reviewed. As demonstrated by these examples, both climatic and tectonic processes have influenced the formation of fluvial terraces over time periods of tens to hundreds of thousands of years during the Quaternary period. The studies cited here used various methods of absolute and relative dating, including cosmogenic nuclide exposure dating, radiocarbon dating, correlation to dated tephra and loess stratigraphies, optically stimulated luminescence (OSL) dating, and relative age dating from degree of soil development and thickness of weathering rinds on gravel clasts.

Types of Fluvial Terraces and Terrace Terminology

The two basic types of fluvial terraces are aggradational and degradational ([Figure 1](#)). Aggradation, or net deposition of sediment along a river channel and its floodplain over a prolonged period of time, leads to the formation of an alluvial fill terrace. At the crossing of a geomorphic threshold from either deposition or stability (i.e., no net deposition) to net degradation, alluvium is incised and a fill terrace is both created and abandoned ([Bull, 1991](#)). Radiocarbon dating of organic matter in alluvium from an aggradational terrace along Cajon Creek, a stream that crosses the San Andreas fault in southern California, USA, reveals that it can take as long as 10 ka for aggradation to form a fill terrace over a distance of ~10 km ([Weldon, 1986](#)). Furthermore, the time since the onset of filling, abandonment, and incision decreases upstream along Cajon Creek, indicating a time-transgressive terrace surface.

If incision of an aggradational terrace is punctuated by pauses that allow the stream to cut laterally rather than vertically, then cut terraces are carved into alluvial fill. Cut terraces (sometimes called cut-fill) have a distinctly different origin than the higher fill terrace into which they are carved. It is possible that a subsequent cycle of aggradation and degradation might begin again after some period of vertical downcutting, resulting in an inset fill terrace that is difficult to distinguish from a cut terrace. Only careful stratigraphic work and dating can help to make the distinction between the two possible origins of the terraces.

Lateral cutting of bedrock followed by vertical degradation, or incision, results in the formation of a strath terrace. When abandoned, the floodplain associated with the bedrock stream is left behind as well, leaving a veneer of coarse sediment on the strath surface that is proportional to the scour depth and bedload thickness associated with bankfull discharge (e.g., [Lavé and Avouac, 2001](#); [Pazzaglia and Brandon, 2001](#)). Whereas the coarse sediment on a strath is generally thought to have been associated with bedload transport, the finer sand, silt, and clay often capping a strath and its gravel veneer probably are deposited by a combination of overbank sedimentation during high-magnitude floods ([Merritts et al., 1994](#)) and colluvial deposition from side slopes ([Lavé and Avouac, 2000](#)).

Through extensive radiocarbon dating of strath terrace sediments, [Merritts et al. \(1994\)](#) have shown that overbank deposition of fine sediment can occur during rare, high-magnitude floods several thousand years after a strath is formed by incision and abandonment of a river's previous channel level. The duration of overbank deposition after strath formation depends on the rate of vertical incision and the stochastic distribution of floods along the river, with low rates of incision and large-magnitude floods favoring the possibility of episodic deposition on the older surface.

Causes and Processes of Fluvial Terrace Formation

Fluvial terraces are formed by one or more changes in three dominant controls on a river's longitudinal profile: base level, water discharge, and sediment supply. When one or more of these factors changes, the river adjusts its channel to the new conditions and sometimes forms a new channel bed and floodplain at a lower or higher level than the original ones. Changes in the controlling parameters of discharge, sediment supply and caliber, or base level essentially are perturbations that lead to waves of erosion or deposition that can propagate along a stream.

Changes in base level (and local gradient) occur primarily through tectonic processes, as with rock uplift, differential tilting, faulting, and folding. Changes in water discharge and sediment supply occur primarily through changes in prevailing

Figure 1 Valley cross-section illustrating a complex sequence of aggradational and degradational (cut and strath) terraces. The history of aggradation and degradation that led to the terrace sequence is outlined in the hand box. Reproduced from Burbank DW and Anderson RS (2001) *Tectonic Geomorphology*, p. 274, Figure 2.11C. Oxford: Blackwell Science.

climatic conditions, which affect vegetation type and cover, and rates of soil erosion and runoff of water from upland slopes. For example, when falling sea level or an uplifting land mass lowers the relative base level of a coastal river and increases the river's gradient near the coast, the river incises and abandons its former floodplain level, leaving a terrace remnant that records the earlier position and gradient of the channel and floodplain. If a cooling climate results in a decrease in vegetation cover on slopes and an increase in sediment supply that exceeds stream-carrying capacity (or perhaps a decrease in effective discharge), then aggradation might occur along the river channel and floodplain. Aggradation continues until the stream gradient is sufficiently steep to transport the prevailing load of incoming sediment. When aggradation ceases, perhaps during subsequent warming and an increase in vegetation cover, the fill surface is abandoned and incised, producing a fill terrace at a higher elevation than the original channel and floodplain.

Previous workers have recognized that a stream can adjust to carry the flux of water and sediment by altering its width, depth, roughness, and/or gradient (Leopold and Bull, 1979). We are most interested in the last of these, adjustments in channel gradient, as these lead to terrace formation. The adjustment of channel long profiles by aggradation or degradation is thought to occur because streams maintain an equilibrium long profile, or graded profile, over sufficiently long time periods (graded timescale of Schumm and Lichty (1965)). A graded stream is one that has sufficient stream power to transport sediment and water supplied from upstream, without aggrading or degrading along its bed (Bull, 1991; Knox, 1975; Leopold and Bull, 1979; Mackin, 1948). In general, long-term degradation of the channel bed and floodplain occurs if stream power is decreased (e.g., decreased discharge or gradient) or if the ability to transport sediment is reduced (e.g., increased bed roughness or grain size).

The graded stream is thought to evolve toward a steady-state profile in which rates of rock uplift and river incision are closely balanced along the length of the long profile of the stream (Bull, 1991; Burbank et al., 1996; Pazzaglia and Brandon, 2001; Pazzaglia et al., 1998). This close connection between uplift and incision implies that the difference in elevation between long profiles of streams and terraces can be used to assess rock uplift, much as marine terraces are used to assess coastal uplift.

Terraces often form during vertical incision by knickpoint, the process by which a steepened reach of channel – the knickpoint – propagates upstream (Gardner, 1983; Zaprowski

et al., 2001). As the knickpoint propagates upstream, it leaves an abandoned strath or cut surface in its wake downstream, such that the degradational terrace is graded to the crest of a knickpoint and is time transgressive in age (Merritts et al., 1994; Seidl and Dietrich, 1992). Experimental work has shown that the rate of knickpoint migration is proportional to discharge, with migration rates diminishing toward head-water reaches. Studies that utilize cosmogenic nuclide exposure dating indicate that knickpoints formed in basalt in Hawaii have migrated upstream at rates of $>2 \text{ mm year}^{-1}$ (Seidl et al., 1994), whereas those cutting metamorphic and igneous rocks in the Himalayan Mountains might be as high as 1 m year^{-1} (Burbank et al., 1996).

Strath terraces in particular have been used as geomorphic markers that record progressive displacement where rivers cross active faults and folds, and in some cases have provided fault slip and fold growth rates (Lavé and Avouac, 2001; Molnar et al., 1994; Rockwell et al., 1984). In the case of faulting that ruptures the surface, each higher terrace records greater displacement than lower terraces (Figure 2).

Case Studies of Terrace Formation

Although both climatic and tectonic processes can drive terrace formation simultaneously, the two can often be separated as they operate over different timescales of change. Long-term rock uplift along a tectonically active margin, for example, might operate at roughly uniform rates over a period of hundreds of thousands to millions of years whereas alternating glacial–interglacial cycles of the Quaternary period have cycles of $\sim 120 \text{ ka}$. While long-term rock uplift drives long-term river incision, shorter-term variations in climate and associated changes in sea level (i.e., base level) might cause episodes of aggradation or accelerated degradation that produce terraces superimposed on the terrace sequence created by the long-term uplift response (see Hancock and Anderson (2002), for a modeling approach to fluvial terrace formation in response to changing climatic conditions).

Tectonically Driven Terrace Formation

We begin the case studies of tectonically driven terrace formation with four examples of long-term incision and strath terrace formation in response to moderate to rapid rock uplift at two tectonically active plate margins: the Himalayan continent–continent collision zone between the Indian and

Figure 2 Offset terrace treads (T1 to T5) reveal the trace of a thrust fault (up on the left) and subsidiary splay in the Tien Shan, Kyrgyz Republic. Each higher, older terrace has displaced successively greater amounts. Deformation of such surfaces can be used to estimate rates of faulting and crustal shortening. Reproduced from Burbank DW and Anderson RS (2001) *Tectonic Geomorphology*, p. 274, Figure 9.6. Oxford: Blackwell Science.

Eurasian plates, and the ocean–continent Cascadia subduction zone boundary between the Juan de Fuca and North American plates. The fifth case study in this section is an example of strath formation in eastern North America, a low-uplift rate passive plate margin where late Quaternary climate change might be the cause of accelerated incision and strath formation superposed on long-term incision that correlates with post-Miocene falling sea level.

Long-Term Incision and Strath Formation, Tectonically Active Plate Margins

Burbank et al. (1996) surveyed and dated strath surfaces along the Indus River near Nanga Parbat in northern Pakistan, where the river crosses the suture zone between the colliding Indian and Eurasian plates in the northwestern Himalayas. Cosmogenic radionuclide exposure ages of seven abandoned strath levels, ranging in height from 65 to 410 m above the Indus River bed (low discharge), span a range in ages from 4 to 68 ka (Figure 3). The terrace ages and altitudes yield corresponding bedrock incision rates that range from 2 to 12 mm year⁻¹, some of the highest known rates of bedrock incision in the world. Apatite fission-track ages along the same river reaches generally yield similar denudation rates, indicating that incision and bedrock uplift appear to be balanced.

Early work in Nepal on rivers flowing southward across the Himalayan Mountains documented that terrace profiles on the hanging wall block above the Main Central Thrust, a south-vergent fault, are tilted down to the north and diverge strongly to the south, consistent with terrace formation above a rising block with differential uplift parallel to the river's long profile (Iwata, 1987). Lavé and Avouac (2000) mapped and radiometrically dated four warped and folded Holocene strath terraces along two rivers draining the Siwalik Hills in central Nepal along the Main Frontal Thrust fault in the foothills of the Himalayas (Figure 4). Combining structural mapping and analysis of active fault bend folding with warped profiles of the dated terraces, they derived rates of bedrock uplift from river incision (as high as 15 mm year⁻¹) and estimated that much of the shortening across the Himalayas is accommodated by the Main Frontal Thrust fault.

Figure 3 (a) Strath terrace remnants, with their cosmogenic nuclide exposure ages and heights above the modern Indus River level in the Himalayas of Pakistan, are shown with apatite fission-track ages from samples taken along the base of the Indus gorge. (b) Incision rates plotted versus distance along the Indus River, with incision rates calculated from cosmogenic nuclide exposure ages. Highest rates correspond with the steepest river gradient. (c) Rates of denudation based on apatite fission-track data and two different geothermal gradients (35 and 60 °C km⁻¹). The zone of maximum long-term denudation coincides with the zone of most rapid river incision. Reproduced from Burbank DW, Leland J, Fielding E, et al. (1996) Bedrock incision, rock uplift and threshold hillslopes in the northwestern Himalayas. *Nature* 379: 505–510.

Figure 4 (a) Strath terraces projected along the Bagmati River in the central Himalayas, Nepal. Strath elevations computed from digital elevation model and field measurements (solid thin lines and dashed lines) are shown with individual field measurements. Solid thick lines represent Holocene terraces, and dashed lines represent hypothetical levels of late Pleistocene terraces that have similar soil color and depth of weathering. Note that terraces are folded above a growing thrust fault at 0–14 km. (b) Topographic and structural cross-sections, with the same horizontal scale, are shown for comparison with the terrace profiles. The terraces reveal sustained Holocene and late Pleistocene activity of the fold growing above the Main Frontal Thrust fault (MFT). In contrast, the terraces indicate that little offset has occurred across the Main Dun Thrust fault (MDT) during the late Quaternary. Reproduced from Lavé J and Avouac JP (2000) Active folding of fluvial terraces across the Siwaliks Hills, Himalayas of central Nepal. *Journal of Geophysical Research B* 105(3): 5735–5770, Plate 7A.

Similar to the work of Personius (1995) in Oregon, USA, and Merritts et al. (1994) (discussed below) in northern California, USA, Lavé and Avouac (2000) obtained much younger radiocarbon dates from silty sediments at the tops of terrace deposits than from underlying gravel veneers resting directly on bedrock straths. Corresponding with the above mentioned US research, the authors concluded that radiocarbon dates from the base of the silt or from within the gravel (bedload) itself are better estimates of the timing of strath abandonment, and attribute the overlying silty sediments to postabandonment depositional processes.

Pazzaglia and Brandon (2001) studied six late Quaternary strath terraces along the Clearwater River in northwestern Washington State, USA, in order to compare long-term uplift and incision rates across the Cascadia forearc high formed inboard of the Cascadia subduction zone. Three approaches were used to constrain terrace ages: weathering rind thickness on graywacke gravel clasts; radiocarbon dating; and correlation to dated coastal glaciofluvial deposits and the global eustatic sea-level curve. Strath terraces formed in the dominantly unglaciated Clearwater drainage while alpine glaciers were advancing in adjacent drainages. During the transition to interglacial

times, an increased sediment supply due to local deglaciation, combined with rising base level at the coast, resulted in aggradation along the Clearwater River. Nevertheless, the river returned to the same valley profile during each cycle of strath-cutting. Bedrock incision rates increase inland from $<0.1 \text{ m ka}^{-1}$ at the coast to $\sim 0.9 \text{ m ka}^{-1}$ near the headwaters in the Olympic Mountains, and are similar to long-term denudation rates estimated from fission-track cooling ages. As incision keeps pace with rock uplift, terraces diverge upstream. Pazzaglia and Brandon (2001) concluded that the Clearwater River valley has maintained a steady-state profile and a long-term balance between incision and rock uplift over a period of tens of thousands of years.

In a region of relatively high uplift rates at the southernmost tip of the Cascadia subduction zone, where the North American, Pacific, and Juan de Fuca plates join at the Mendocino triple junction, Merritts et al. (1994) surveyed and radiometrically dated late Pleistocene and Holocene fill and strath terraces along three rivers in northern California. This work determined that lower reaches of the rivers are dominated by the effects of oscillating sea level, primarily aggradation and formation of fill terraces during sea-level high stands, and deep incision during sea-level low stands (Figure 5). A eustasy-driven depositional

wedge that tapers to zero thickness extends tens of kilometers upstream on all three rivers. In contrast, middle to upper reaches of each river are dominated by the effects of long-term uplift, primarily lateral and vertical erosion and formation of steep, unpaired strath terraces exposed only upstream of the depositional wedge. Vertical incision at a rate similar to that of uplift ($1\text{--}2 \text{ m ka}^{-1}$) has occurred even during the present sea-level high stand along the two rivers with highest uplift rates. Strath terraces have steeper gradients than the modern channel bed and do not merge with marine terraces at the river mouths.

Long- and Short-Term Incision and Strath Formation, North American Passive Plate Margin

Three ongoing processes have produced a relative, long-term base-level fall at the mouth of the Susquehanna River along the eastern North American passive plate margin: (1) flexural up-warping of the Appalachian Piedmont in response to denudational unloading in the Susquehanna watershed, (2) downward flexural warping offshore in response to sediment deposition on the continental shelf, and (3) protracted eustatic sea-level fall beginning in the middle Miocene

Figure 5 Longitudinal profiles of channel bed, water surface, strath surfaces, and treads of fill terraces from detailed total geodetic station along the Mattole River, northern California. Treads of cut-and-fill terraces are indicated by fine lines (hundreds of survey points not shown), dashed where correlations are tentative, while strath surfaces are indicated by both heavy lines, dashed where correlations are tentative, and survey points (crosses). Stippled pattern downstream of 18 km indicates alluvium where depth can be estimated from well data (drill holes shown as 1, 2, and 3). Multiple unpaired strath terraces occur upstream of 18 km, shown by a bedrock surface (heavy line) and overlying alluvial tread (fine line). Deposits are shown as stippled pattern at several sites to indicate corresponding straths and treads, but not all are included because straths and treads overlap one another. Radiocarbon dates are centroids of calibrated age ranges in years before present. Relative sea level (RSL) is determined from both sea-level change and landmass uplift. Reproduced from Merritts DJ, Vincent KR, and Wohl EE (1994) Long river profiles, tectonism and eustasy: A guide to interpreting fluvial terraces. *Journal of Geophysical Research* 99: 14031–14050.

Figure 6 (a) Strath terrace levels 1 and 3 in the Holtwood Gorge along the Susquehanna River at low flow conditions. Level 2 is not preserved at this location. At higher discharges, strath level 1 is submerged. (b) Paleogradients for strath terrace levels 1, 2, and 3 and a prominent watermark in July 2002, were acquired with differential global positioning system (GPS). The watermark is representative of the modern river gradient. (c) The timing of incision and terrace abandonment within Holtwood Gorge is shown diagrammatically with respect to time (x-axis) and in relation to documented changes in climate and sea level. Reprinted from Reusser LJ, Bierman P, Pavich M, Larsen J, and Finkel R (2006) late Pleistocene bedrock channel incision along the U.S. Atlantic passive margin, Holtwood Gorge, Susquehanna River, Pennsylvania. *American Journal of Science*, Figures 4A, 5, and 17A, with permission from the American Journal of Science.

(Pazzaglia and Gardner, 1993; Pazzaglia et al., 1998). The unglaciated, lower Susquehanna River has a convex upward long profile with steep gradients as a result of these processes. Recent cosmogenic exposure dating of three low strath terraces (referred to as levels 1–3) within the Holtwood Gorge along the lower Susquehanna River indicates that rates of vertical incision dramatically increased between ~ 35 and $\sim 14 \text{ ka}$ (Figure 6). Prior to $\sim 35 \text{ ka}$, maximum vertical incision was $\sim 0.2 \text{ m ka}^{-1}$, but from ~ 35 to $\sim 20 \text{ ka}$ the rate of incision accelerated to 0.45 m ka^{-1} . The rate of incision increased again to $\sim 0.52 \text{ m ka}^{-1}$ between ~ 20 and $\sim 14 \text{ ka}$, when significant incision ceased. An upstream-younging age gradient of $\sim 1.4 \text{ ka km}^{-1}$ on the level 2 terrace is consistent with knick-point retreat, but no significant time-transgressive relationship exists on either the highest (level 3) or lowest (level 1) terraces, suggesting that these surfaces were abandoned rapidly along the length of the Holtwood Gorge.

Reusser et al. (2004) interpret the high rates of late Pleistocene incision to be the result of a prolonged period of climate instability from ~ 45 to 14 ka , and the cessation of rapid

incision to correspond with the transition from Pleistocene full-glacial conditions to the warmer, more climatically stable Holocene Epoch. Using climate data for the North Atlantic region, they note that a marked increase in storminess beginning at $\sim 50 \text{ ka}$ and lasting until $\sim 10 \text{ ka}$ correlates well with the initiation and cessation of incision within Holtwood Gorge. Furthermore, they suggest that increases in the frequency, magnitude, and duration of flood events that are capable of exceeding critical geomorphic thresholds for detachment of rock might have increased rates of bedrock channel incision during the last glacial cycle. Because of the timing of increased incision, they conclude that climate is likely to be a more important external factor than the low sea level and base-level fall associated with full-glacial episodes.

Climatically Driven Terrace Formation

The previous example indicates that incision driven by long-term, slow uplift and relative sea-level fall can be accelerated

during cold conditions, as during full-glacial episodes, but many studies in other areas have documented a switch from incision to aggradation during previous glacial periods. [Blum and Tornqvist \(2000\)](#) have reviewed this mismatch between the role of climate and sea level in aggradation and degradation of coastal fluvial systems. Paired aggradational terraces throughout the world have been associated with Quaternary glacial-interglacial cycles, with aggradation commonly thought to have occurred during glacial periods and incision during subsequent warmer periods (cf. [Bridgland, 2000](#); [Penck and Brückner, 1999](#)). In some cases, fill terraces were correlated with glacial moraines and interpreted to be of similar age regionally, so they were correlated with one another among basins, even on unglaciated rivers. Recent work on nonglaciated streams in New Zealand supports the premise of these earlier studies,

and is described here as an example of regional aggradational terrace formation driven by climatic change. Other examples of aggradational river terraces documented to have been formed by Quaternary climate change in nonglaciated regions are described in [Bull \(1991\)](#).

Terrace Formation during Quaternary Glacial–Interglacial Cycles

Along the actively uplifting Hikurangi Margin along the eastern side of the North Island in New Zealand, [Litchfield and Berryman \(2005\)](#) and [Litchfield and Rieser \(2005\)](#) extended the results of previous studies to correlate four aggradational terraces among eight nonglaciated drainage basins ([Figure 7](#)). The work of [Litchfield and Rieser \(2005\)](#) represents one of the

Figure 7 (a) A suite of fill (T1 and T2) and cut terraces along a river on the North Island of New Zealand. The gravel of T2 is visible above a strath cut into early Pleistocene siltstone bedrock (white). (b) Schematic cross-section illustrating the relations among the terraces and overlying loess and tephra coveredbeds. Reproduced from Litchfield NJ and Berryman KR (2005) Correlation of fluvial terraces within the Hikurangi Margin, New Zealand: Implications for climate and base-level controls. *Geomorphology* 68: 291–313, Figure 3. Copyright 2005 with permission from Elsevier.

most extensive analyses of the use of OSL dating for river terraces. OSL dating measures the time that has elapsed since sediment was last exposed to light, presumably at the time of deposition. [Litchfield and Rieser \(2005\)](#) used it for both silts and sands near the tops of aggradational terraces, and for loess coverbeds overlying the terraces.

Based on consistent results from tephra chronology, loess stratigraphy, radiocarbon dating, and OSL dating, terrace ages are linked to the following late Pleistocene dry, cool stadial, and/or glacial periods: 15–30, 31–40, 55–70, and 115 ka. These results confirm that aggradation and loess deposition were widespread on the North Island of New Zealand during both full glacial and interstadial periods. As each aggradational terrace formed, the riverbed was the source of loess blown onto higher terraces, so that each higher, older terrace has one more loess cover deposit than the next lower aggradational terrace. [Litchfield and Berryman \(2005\)](#) conclude that limited grass and shrub vegetation cover, combined with periglacial processes, produces an increased sediment supply that led to the widespread aggradation associated with cool periods, whereas reestablishment of forested slopes during postglacial periods led to incision of fill deposits, producing abandoned fill terraces.

Since the formation of the lowest aggradational terrace, T1 at 15–30 ka, when global eustatic sea level was at its lowest (~ 120 m), North Island streams have been degrading and carving strath terraces into bedrock, despite a rising Holocene sea level. The intriguing conclusion in this region is that climatic controls on sediment and water discharge are more significant to terrace formation than rising or falling base levels.

Cycles of Aggradation and Degradation in Arroyos of the Semiarid American Southwest

Currently incised channel systems in the semiarid, nonglaciated southwestern United States, known as arroyos (Spanish for gulch), have repeatedly aggraded and incised during the Quaternary period, leaving a complex record of cut-and-fill terraces (cf. [Bull, 1991](#); [Cooke and Reeves, 1976](#)). Modern arroyos currently are in a phase of cutting that dates to the nineteenth century, possibly due to grazing and other recent land-use changes, and carry large volumes of sediment during ephemeral to intermittent flows ([Cooke and Reeves, 1976](#)). During repeated episodes throughout the Quaternary period, however, arroyos have been unable to transport their sediment load and have aggraded, forming fill terraces.

Decades of investigations of arroyos have led many workers to attribute the cyclicity of arroyo filling and incision to alternations between relatively wet, pluvial climates during glacial periods and drier climates during interglacial and interstadial periods. Wetter conditions are thought to be associated with production of greater sediment yields from upland slopes (e.g., [Bull, 1991](#)). However, full understanding of the 'arroyo cycle' is complicated by the fact that repeated cycles of cutting and filling have occurred during the Holocene interglacial warm period ([Cooke and Reeves, 1976](#)). Some regional forcing mechanism is thought to be responsible for generally synchronous episodes of cutting and filling that extend over broad areas. Some workers have suggested that complex interactions

within arroyo systems, as well as the initial state of the arroyo system at the onset of climatic change, are critical to the response of arroyos to climatic forcing (cf. [Schumm et al., 1984](#)).

Conclusions

Recent studies of long profiles of rivers and fluvial terraces have illuminated the relation between crustal and surficial processes of uplift and incision, respectively. As described in four examples herein, researchers used altitudinal differences between dated straths and the modern channel to estimate rates of vertical incision at a given stream reach, and then compared these estimates with rates of rock uplift or denudation that were derived independently ([Burbank et al., 1996](#); [Lavé and Avouac, 2001](#); [Merritts et al., 1994](#); [Pazzaglia and Brandon, 2001](#)). In all four cases, the rates of uplift and incision are roughly balanced, supporting earlier ideas of steady-state long profiles for graded streams that are adjusted to long-term uplift. While these four examples were in areas of relatively high rates of uplift along tectonically active plate margins, a recent study along the eastern North American passive margin, on the lower Susquehanna River, provides clues to the effect of climate change on river incision. Cosmogenic exposure dating of strath surfaces indicates that relatively short-term climatic change which leads to colder and possibly stormier conditions can result in pulses of accelerated incision, even where long-term uplift rates are low.

Although the Susquehanna River example links glacial climatic conditions to accelerated bedrock incision and strath abandonment, numerous studies in Europe, North America, and New Zealand have documented a switch from incision to aggradation during glacial conditions. [Merritts et al. \(1994\)](#) and [Pazzaglia and Brandon \(2001\)](#), in contrast, describe aggradation during Late Glacial and interglacial times along lower reaches of the coastal rivers that they studied. [Blum and Tornqvist \(2000\)](#) have reviewed this mismatch between the role of climate and sea level (i.e., base-level change) in aggradation and degradation within coastal fluvial systems. One of the best constrained examples, with extensive dating using multiple techniques that include radiocarbon dating, tephra chronology, loess chronology, and OSL dating, is described here for North Island, New Zealand ([Litchfield and Berryman, 2005](#); [Litchfield and Rieser, 2005](#)). This work demonstrates conclusively that regional aggradation occurred along coastal rivers during full-glacial times, regardless of a markedly lower sea level, and that the Holocene is marked by incision and the formation of cut and strath terraces.

As with the case of the cycles of arroyo cutting and filling described here, it might be that each river system responds differently to climate change, depending on its initial conditions at the onset of external change and on the magnitude of change in sediment supply from upland slopes. Where relief is high and slopes are steep, as in New Zealand, climate cooling and periglacial conditions seem to overwhelm streams with sediment, whereas the low-uplift Susquehanna River basin, with generally low relief and gentle upland slopes, does not generate sufficient excess sediment to cause aggradation along major trunk streams during cold periods. New techniques of dating terraces and terrace deposits, and multiple new sites

studied around the world, are providing a growing body of evidence that fluvial responses to climate change might be similar regionally, but have significant differences among regions.

Introduction

Definition

Deltas are constructional coastal landforms with both subaerial and subaqueous components that are genetically associated with rivers discharging into a standing body of water such as a lake, estuary, lagoon, sea, or the open-ocean shelf (**Figure 1**). A delta is usually built by a single river, but exceptions exist (e.g., Ganges–Brahmaputra; Tigris–Euphrates). Reworking of sediments accumulated at the river mouth by basinal processes (e.g., waves, tides, and currents) should be slow enough to allow delta building to proceed. The river is the main source for sediment delivered to the delta, although in some wave-dominated settings (e.g., Danube, Sao Francisco, and Rio Doce), a significant portion may be transported by wave-driven currents from remote sources (**Figure 2**).

Importance and Significance of Deltas

Deltas are among the most environmentally and economically important coastal sedimentary environments. Significant oil, gas, and groundwater resources have been exploited from deltaic formations. Historically, modern deltas have been prized by human civilizations for their high natural and agricultural productivity, rich biodiversity, and for the abundance of waterways, which provide easy means of transportation. Deltas are ubiquitous: 21 of the world's 25 largest rivers, which deliver 31% of the total fluvial sediment reaching the ocean, have formed well-expressed deltas at the coast (**Meade, 1996**). As a result, ~25% of the world's population lives within deltaic and wetland coastal systems (**Syvitski et al., 2005**), some in large urban centers such as Shanghai, Bangkok, Dhaka, Saigon, Rangoon, Lagos, Alexandria, Cairo, and New Orleans. River deltas act as filters, repositories, and reactors for a suite of continental materials including sediments, organic carbon, nutrients, and pollutants, significantly affecting both the regional environment at the continent–ocean boundary as well as global biogeochemical cycles (e.g., **McKee et al., 2004**). However, deltas are fragile geomorphic features that can change dramatically with modest modifications in their boundary conditions. Currently, the largest threat to the world's deltaic systems is the trapping of sediment behind dams erected on delta-building rivers and their tributaries. Deltas also face the threat of accelerated relative sea-level rise due to climate change and fluid extraction.

History of Delta Research

The term 'delta' was introduced by Herodotus (fifth century BC), by analogy to the Greek letter Δ, to describe the shape of the lowlands between the forking distributaries of the river Nile in Egypt (**Figure 1(g)**). In 1832, in his *Principles of Geology*, Charles Lyell first defined the modern geological meaning of

the term 'delta' as 'an alluvial land, formed by a river at its mouth, without reference to its precise shape.' The first comprehensive review of modern deltas was written by Credner in 1878, wherein the author correctly identified many of the processes affecting the form, structure, and evolution of deltas. Early landmark papers on deltas also include those of **Gilbert (1885)**, **Fisk et al. (1954)**, and **Wright and Coleman (1973)**, among others.

In the 1980s, research on deltas moved from the development of depositional models based on modern highstand deltas, which are ultimately controlled by the delta-building rivers, to sequence stratigraphic interpretations of deltaic evolution through multiple sea-level cycles (e.g., **Van Wagoner et al., 1988**). More recent research on modern deltas has been spurred by concerns related to human influences on the larger riverine systems, either directly through damming and water consumption, or indirectly via climate changes. Historical stages in deltaic research can be followed in successive comprehensive volumes edited by **Morgan (1970)**, **Broussard (1975)**, **Oti and Postma (1995)**, and **Giosan and Bhattacharya (2005)**, as well as periodic review papers such as **Bhattacharya and Walker (1992)**.

River Deltas

Controls and Processes

The stratigraphic architecture of deltas is the end result of complex interactions among upstream catchment processes that regulate the location and magnitude of the fluvial sediment discharge, and downstream basinal controls that include the shape and quantity of accommodation space for sediment accumulation and the type and energy of coastal processes that redistribute these sediments. Together, all of these controls determine the mode and degree of partitioning of sediment between the delta and the wider receiving basin (e.g., **Wright and Coleman, 1973**).

The sediment discharge of a river is determined by (1) climate that regulates the precipitation–evaporation characteristics of the watershed, and thus water flow; (2) the nature and abundance of vegetation that may inhibit erosion; and (3) the tectonic regime and lithology that determines elevation, slope, and degree of erodability of rocks in the watershed. Geology also controls the water gained or lost by a river as groundwater. Accommodation space in the receiving basin is dependent on (1) the relief characteristics of the basin, such as the extent of the shallow sector of the basin (or shelf) and (2) the degree of connection to the open ocean (e.g., a closed lake, indented estuary, or a straight coast). Such basin characteristics may also change drastically as variations in base level expose more or less of the margin. Base-level changes during the Quaternary were predominantly driven by the growth and

decay of continental ice sheets, but in the case of enclosed basins such as the Black Sea and Caspian Sea, major base-level changes were forced by climatically driven fluctuations in their water budget. Additional components of relative base-level change are caused by tectonics, compaction, and isostasy.

Sediment in suspension is discharged as a plume at the river mouth, which is the single most important location for partitioning of sediment between the delta and the basin. Some rivers also transport a significant fraction of coarse bedload sands to the coast, where these less mobile sediments are

preferentially stored within the delta edifice. As the river plume enters the receiving basin, flow expansion and deceleration exert a strong control on river-mouth sedimentation, which is dependent on the outflow inertia, turbulent bed friction, and plume buoyancy. The latter may be positively, neutrally, or negatively buoyant, depending on the density contrast between the plume and basin waters. Waves and tides are also important in controlling deposition at a river mouth, especially in high-energy coastal settings. Tidal and wind-driven currents, as well as Coriolis rotation, may strongly

Figure 2 Morphology and depositional environments of the Danube delta in the Black Sea: (a) channels and natural levees; (b) sandy beach ridges; (c) floodbasins, lakes, and lagoons; and (d) delta lobes (the box indicates the location of Chilia III lobe described later in [Figure 5](#)). The delta started as a bayhead delta (Tulcea lobe), followed by the development of other fluvial-dominated lobes in shallow lakes, and lagoons left unfilled by the Tulcea lobe (Chilia I and II; Dunavatz). Once reaching the open coast, several wave-dominated (St. George I and II and Sulina) or fluvial-dominated (Chilia III) lobes formed. Note that the sand comprising the beach-ridge plains built updrift of open coast lobes was delivered via the longshore drift system. Reproduced from Giosan L, Donnelly JP, Vespremeanu E, and Buonaiuto FS (2005) River delta morphodynamics: Examples from the Danube delta. influence the behavior and path of the plume after exiting the river mouth region. The relative importance of these processes, as well as their history (i.e., frequency of occurrence and intensity), are also important in determining the patterns of sediment deposition across the delta and, ultimately, its stratigraphic architecture.

Delta Sediments, Morphology, and Morphodynamics

Deltas are complex sedimentary systems comprising a multitude of depositional environments. At the apex of the delta plain, which is the subaerial part of a delta, the river usually bifurcates into distributaries that, in many cases, can build

their own delta lobes (Figure 2). The number of lobes tends to decrease in wave-dominated settings where the number of distributaries is minimal. Lobes can rarely be distinguished in settings where tides are strong, because tidal currents favor channel stability and suppress avulsions. The entire delta can sometimes change location through large-scale avulsions to build separate subdelta complexes. This is the case for the Huanghe (Yellow) River, which completely switched its course at least twice to build deltas in both the Bohai and South Yellow seas (Saito et al., 2001). The Mississippi River has also built six separate subdeltas comprising 16 individual lobes (see review in Roberts, 1997).

Based on general morphology of the subaerial delta plain, deltas have typically been classified as fluvial, wave, or tide dominated according to the dominant processes affecting sediment delivery, deposition, and dispersal (Figure 3; Galloway, 1975; Orton and Reading, 1993). A typical fluvial-dominated delta has an elongate to lobate plan-view morphology with highly crenulated shorelines; mouth bar and channel fill sands are interspersed within fine-grained deposits of the interdistributary region. In contrast, classic wave-dominated deltas assume a cusped morphology and are mainly composed of beach-ridge sands. Tide-dominated deltas, which appear mostly irregular in plain view, are primarily composed of estuarine and tidal shoals, or islands, flanked by mudflats.

However, a continuum of settings with overlapping processes rarely makes this classification operational at a scale larger than an individual delta lobe (Bhattacharya and Giosan, 2003). Even at the lobe scale, an in-depth look at wave influence on deltas shows that morphology and facies distribution is dependent more on the influence of the wave-driven long-shore sediment transport relative to fluvial discharge, rather than on wave energy itself (Figure 4). In multilobe deltas, one lobe may assume a vastly different morphology than an adjacent lobe. Of the two youngest lobes of the Danube delta, the Chilia, which is built with ~60% of the river-sediment discharge, is fluvial dominated, whereas the St. George is clearly wave dominated (Figure 2). Temporal variability in sediment discharge or basin energy can also result in drastic morphological changes in a delta/lobe (Giosan et al., 2005). The Po delta lobes had been wave dominated before a drastic increase of sediment discharge during the Little Ice Age (ca. AD 1450–1850) resulted in a fluvial-dominated outbuilding phase (Correggiari et al., 2005). Even without changes in total sediment discharge, the developing Chilia lobe of the Danube delta started to show morphological modifications typical of wave-influenced settings (e.g., straightening of the shoreline, buildup of barrier spits and islands) due to a decrease in sediment delivered by the river per unit shoreline (Figure 5).

Figure 3 Process-based ternary classification of delta morphology as a function of fluvial discharge and wave and tidal energy. Satellite images of deltas are from Google Earth (<http://earth.google.com/>; Balize, Ebro, Mahakam, Grijalva, and Copper images © MDAEarthSat and DigitalGlobe; Ganges–Brahmaputra image © MDAEarthSat). Reproduced from Galloway WE (1975) Process framework for describing the morphologic and stratigraphic evolution of deltaic depositional systems. In: Broussard ML (ed.) *Deltas: Models for Exploration*. Houston, TX: Houston Geological Society.

Figure 4 Morphology and depositional environments for mud-rich wave-dominated deltas as a function of the ratio between longshore drift and fluvial discharge (relative magnitudes indicated by black and white-filled arrows, respectively). Unlike the classical symmetric wave-dominated deltas, where sediment supplied by the feeding river is reworked on either side by waves, asymmetric deltas develop where the longshore drift becomes important relative to the river discharge and updrift beach-ridge plains develop. The downdrift side is a succession of elongate sandy ridges separated by mud-filled troughs. The mouth of the river gets deflected in extreme cases of asymmetry resulting in a series of quasiparallel sand spits and channel fills. Reproduced from Bhattacharya JP and Giosan L (2003) Wave-influenced deltas: Geomorphologic implications for facies reconstruction. *Sedimentology* 50: 187–210.

Figure 5 Delta-plain evolution of the Chilia III lobe of the Danube delta. The morphology of the lobe had been fluvial dominated until recently, when the coast began to straighten and barrier spits and islands started to develop along the coast (indicated by arrows). (Satellite image from Google Earth: <http://earth.google.com/>; © MDA EarthSat and DigitalGlobe.) Reproduced from Giosan L, Donnelly JP, Vesprieanu E, and Buonaiuto FS (2005) River delta morphodynamics: Examples from the Danube delta. In: Giosan L and Bhattacharya J (eds.) *River Deltas: Concepts, Models, Examples*, pp. 393–411. Tulsa, OK: SEPM. Special Publication 83.

Delta morphology is also greatly controlled by the geometry of the receiving basin (Wright and Coleman, 1973). Because tides are absent in lakes, lacustrine deltas (Figure 1(a)) are either fluvially dominated, when they build in shallow, low-energy lakes, or may become wave dominated in larger lakes (Figure 1(b)), where a longer fetch allows larger waves to form. Bayhead and lagoonal settings are typically low-energy environments that favor fluvial and tidal influences over the effect of waves (Figure 1(c)–1(e)). Morphology of deltas building along straight, open coasts is strongly dependent on the shelf configuration (i.e., width, steepness), which changes not only with the type of continental margin (i.e., active vs. passive) but also with sea-level changes that regulate the vertical accommodation space and the degree of coastal indentation. For example, as deltas prograde toward the middle and outer shelf, their morphology may be affected by increasing wave influence associated with deeper nearshore waters. In contrast, a broad, low-gradient inner shelf can attenuate incident waves and amplify tides, thereby favoring more tidally influenced delta systems.

In cross section, the idealized delta morphology and stratigraphy has been described as a prograding clinoform composed of an upward coarsening facies succession that starts with a basal muddy prodelta, progresses into a sandy delta front and is topped by texturally variable delta plain deposits (Figure 6). The subaqueous portion of a delta comprises both the distal prodelta and the steeper, prograding delta front, whereas the delta plain is predominantly subaerial. The muddy prodelta itself often acquires a ‘clinoform’ geometry, leading to a compound clinoform architecture for the delta that consists of a nearshore sandy clinoform associated with the shoreface and an offshore muddy clinoform (Figure 7) associated with the prodelta (Kuehl et al., 2005). Development of prodelta clinoforms is not universal and appears to be a function of fluvial input and basin hydrodynamics (Swenson et al., 2005). In such settings, gravity-driven flows of suspended mud commonly feed the growth of prodelta clinoforms in the presence of episodic or periodic high-energy processes, such as spring-neap tidal cycles or during storm events.

Figure 6 Idealized cross-section showing internal bedding geometry and facies architecture of a prograding deltaic clinoform. Reproduced from Gani MR and Bhattacharya JP (2005) Lithostratigraphy vs. chronostratigraphy in facies correlations of Quaternary deltas: Application of bedding correlations. In: Giosan L and Bhattacharya J (eds.) *River Deltas: Concepts, Models, Examples*, pp. 31–48. Tulsa, OK: SEPM. Special Publication 83.

Figure 7 Digital elevation model for the Indus shelf based on the nineteenth century surveys showing the compound clinoform morphology for the subaqueous Indus delta. The nearshore clinoform extends to the ~10 m isobath. Offshore clinoform lobes are indicated by arrows. Inland geography is visualized on a satellite image from 2000 (the limits of the Indus delta and the adjacent mud flats of the Great Rann of Kutch are indicated by the white dashed line).

Morphodynamic response in deltas involves feedbacks between the evolving morphology of a delta and its fluvial and basal hydrodynamics. Early models identified rotation of the shoreline as responsible for changes in longshore drift along

deltaic coasts and affecting the rate of progradation. Asymmetry of the wave climate increases the shoreline instability on the downdrift delta wing, promoting development of spits detached from the main delta coast (Bhattacharya and Giosan, 2003).

Hydrodynamic–morphodynamic feedback loops have also been identified in relation to bedload sedimentation at river mouths. The hydraulic groin effect of river plumes is accompanied by the groin effect of the subaqueous delta or of the delta plain, blocking longshore drift at the river mouth (Giosan et al., 2005). On the downdrift wing of asymmetric wave-dominated deltas, periodic emergent barrier islands provide steep, continuous shorefaces for the longshore drift, leading to rapid expansions of the subaqueous delta in the alongshore direction.

Deltas in the Quaternary

Whereas waves and tides are key controls of deltaic systems over decades to centuries, delta evolution at longer timescales is most significantly controlled by (1) sea level, (2) climate, and (3) tectonics. Changes in these first two controls, sea level and climate, are hallmarks of the Quaternary period and its succession of glacial and interglacial phases. As a consequence, deltaic systems have effectively experienced continuous cycles of formation, change, and destruction throughout the Quaternary. Because the major controls of sea level, climate, and tectonics are interrelated, their relative impacts on deltaic systems remain unclear (Goodbred, 2003). Nevertheless, traditional models posit that the development of major deltaic systems is restricted to periods of sea-level highstand, with flooded continental margins and slow to moderate rates of sea-level rise. However, in the past few decades Quaternary deltaic systems have been discovered at a variety of shelf positions and been linked to numerous states of sea-level change. In the past two decades, the advent of multibeam sonar imaging and improved seismic reflection processing has allowed such deltaic shelf deposits to be discovered. A growing knowledge of climate history has in many cases provided explanations (e.g., high sediment supply due to increased precipitation, geomorphic landscape disequilibrium) for delta formation even under rapid rates of sea-level rise.

Influence of Climate on Deltas

Deltas can largely be considered a function of (1) riverine water and sediment discharge to the continental margin and (2) the interaction of these fluxes with coastal and marine processes. In this way, climate plays a major role in both the catchment-based forcing of sediment production and fluvial transport and the modulation of sea level and coastal weather conditions in the receiving basin. As such, there is strong climatic overprinting on deltaic systems, but precise signals are difficult to quantify because of complex feedbacks and secondary influences.

In the terrestrial realm of a fluviodeltaic dispersal system (i.e., the fluvial catchment) perhaps the most prevalent role that climate plays lies in controlling precipitation. With regard to sediment production, precipitation is a primary control on glacial and fluvial incision, weathering, and slope failure. Although highly variable, sediment is readily produced across a range of climates, from arid to humid and polar to tropical. However, one of the main factors that differs among these settings in terms of climate is runoff (=precipitation – evapotranspiration) and thus, the ability to transport sediment

to the delta. In other words, sediment can be produced in many settings, but is most efficiently transported given sufficient water discharge, which is primarily controlled by climate.

Other important characteristics of precipitation include its phase (liquid vs. frozen), seasonality, and episodicity. First, the phase of precipitation controls the relative role of glacial and fluvial erosion in sediment production, as well as the timing and nature of water discharge (i.e., the hydrograph). Each affects sediment-load grain size and weathering characteristics and, hence, the downstream development of delta stratigraphy. Second, the seasonality of river discharge affects the relative interaction of fluvial and marine processes, whereby strongly seasonal systems are subject to specific periods of river and marine-dominated conditions during the year. Similarly, the episodic discharge typified by storm-dominated or semiarid river systems leaves a strong imprint on deltas, because sediments are delivered in large but infrequent pulses. Finally, precipitation exhibits a strong secondary control on delta systems through the type and density of catchment vegetation, which affects runoff via overland flow and evapotranspiration rates as well as soil erosion rates.

From the marine side of a delta, climate change plays the primary role in modulating eustatic sea level through the orbitally controlled advance and retreat of continental ice sheets. This waxing and waning of ice sheets, a defining characteristic of the Quaternary period, has forced repeated, generally rapid, large-magnitude cycles of sea-level change. For delta systems, being principally coastal features, such glacioeustatic changes in sea level have been a first-order control on their development. In this way, traditional conceptual models suggest that prominent delta systems form only under relatively stable sea-level conditions and more specifically during highstands when fluvial sediment is likely to be trapped on the inner shelf. In contrast, during lowstands of sea level it was considered that most fluvial sediment was discharged beyond the shelf edge, either by off-shelf transport of gravity flows or through bypassing via canyon systems. Intervening periods of sea-level rise were assumed to preclude the development of deltas because of rapid coastal transgression or regression.

Site Cases from the Quaternary

Until recently, few studies have specifically investigated climate signals and impacts in delta systems. The current knowledge base on this subject comes from several modeling groups, some field studies, and also by revisiting existing data with a better understanding of climate change provided by secular records (e.g., loess deposits, speleothems, and lacustrine sediments). Although the site cases discussed below are not exhaustive, two relevant trends emerge. First, the number of modeling studies equals or exceeds those based on field investigations, and second, the majority of delta systems in which climate has been investigated are located in the subtropics (the Rhine/Meuse a notable exception). Subtropical systems tend to be highly seasonal, receiving nearly all of their precipitation during the wet summer monsoon when the intertropical convergence zone (ITCZ) is most proximal. At orbital timescales, both the position and strength of the ITCZ vary in response to global boundary conditions (i.e., extent of continental ice sheets) and maximum summer insolation,

respectively. Thus, such systems have exhibited among the most prominent responses to Quaternary climate variability.

Yellow river delta

Extensive databases from a few areas of the world have led to the discovery of significant deltaic deposits on the middle and outer portions of the shelf (see e.g., [Figure 7](#)). In the North Yellow Sea, a compilation of seismic data by [Liu et al. \(2004\)](#) detailed a massive deltaic clinoform comprising $\sim 400 \text{ km}^3$ of sediment from the Yellow (Huanghe) River. The Shandong mud wedge, as the feature is known, is 20–40 m thick and situated on the mid-shelf at water depths of 30 to $>50 \text{ m}$. Prominent within the deposit is a marine flooding surface that indicates the delta formed in two separate stages. Dating of the two phases of transgression and deposition suggests that these responses are associated with rapid changes in the rate of sea-level rise during deglaciation, perhaps related to meltwater pulses. In such case, brief but rapid transgressions were followed by progradation of the Yellow River delta, infilling accommodation space generated by the transgression.

This early Holocene pattern of Yellow River delta formation challenges traditional models in several ways. First, the growth occurs during a period of unstable sea level punctuated by sudden changes, yet the location of primary deposition remains largely unchanged during this time. [Liu et al. \(2004\)](#) ascribe this in large part to the stability of oceanographic circulation patterns in the North Yellow Sea. Second, size and thickness of the delta far exceed that expected for conditions of rapid Postglacial sea-level rise, when models might suggest formation of a thin transgressive sand sheet. In this case, Postglacial transgression in the early Holocene coincided with intensification of the Asian monsoon, and an apparent increase in fluvial sediment discharge. The notion that climatically induced increases in sediment discharge may be sufficient to force delta progradation during rapid sea level opens many new directions for research on how, where, and when such climate–sea level–delta interactions occur.

Ganges–Brahmaputra river delta

The Ganges and Brahmaputra rivers drain the foreslope and backslope of the Himalayan front range, respectively. The two rivers coalesce near the Bengal margin to form the world's largest subaerial delta and deep-sea fan system. The rivers are also strongly driven by the summer SW monsoon, when over 80% of water and 95% of sediments are discharged in the 4–5-month wet season. Given the global significance of the Himalayan/Tibetan uplift and its associated drainage systems, many portions of the Ganges fluvial delta system have been independently investigated in the past 15 years, revealing important variations in glacial activity, alluvial fan and flood-plain development, delta evolution, and regional oceanography. Taken together, the observed patterns show the immense Ganges dispersal system to respond to millennial-scale ($<10^4$ years) climate change in a system wide and largely contemporaneous manner, and major sedimentary signals to be transferred rapidly from source to sink with little apparent attenuation ([Goodbred, 2003](#)).

Some of the major signals of climate change recorded in the delta stratigraphy include (1) a thick (20–30 m) coastal mangrove facies that was deposited during rapid sea-level rise in the

early Holocene and (2) a massive volume of sediment trapped during Postglacial transgression, reflecting a sediment discharge at least 200% higher than the world's largest modern load of 1 billion tons ([Goodbred and Kuehl, 2000](#)). This high-discharge period corresponds to the early Holocene hypsithermal, when peak regional insolation supported a stronger than present monsoon and associated precipitation. In contrast, signals recorded in the delta during the Last Glacial Maximum (LGM) 18–20 ka reflect aridification and very low river discharge. Carbonate ooids, typical of shallow, evaporative tropical waters, formed at this time on the Bengal shelf directly adjacent to the river mouth. Similarly, reconstructed planktonic Foraminifera assemblages from the northern Bay of Bengal (the Ganges receiving basin) indicate peak surface-water salinities and apparently arid conditions at the LGM. These records from the delta and margin correlate well with geomorphic and stratigraphic results from the fluvial catchment, and together reflect the dominance of climate change in controlling this large fluviodeltaic system during the Quaternary ([Goodbred, 2003](#)).

Colorado, Brazos, and Trinity deltas (Gulf of Mexico)

These three rivers comprise a series of small catchments draining the semiarid to moderately humid hills of central Texas, USA and discharging to the northern Gulf of Mexico ([Anderson and Fillon, 2004](#)). Presently, sediment discharge is relatively small and delta progradation is driven by episodic floods associated with humid phases under El Niño conditions. However, during midstands and lowstands of sea level in the late Quaternary, these drainage basins coalesced to form expansive fluviodeltaic sequences on the middle and outer shelf ([Figure 8](#)). The size of these shelf deltas and their connection to underfit streams occupying large fluvial valleys reflect formation under higher-than-present discharge, implying significant changes in past climate.

On the Texas shelf, the position and architecture of relict deltas also indicate their formation during a variety of sea-level stages and transitions. Seismic-based reconstructions of the shelf deposits reveal large, forced-regressive sequences formed during the falling stages of sea level at marine isotope stages 5 and 3 ([Figure 8](#); [Anderson and Fillon, 2004](#)). During these stages, the relative highstand and midstand of sea level, respectively, placed the deltaic lobes near the modern inner to middle shelf. Overlying these regression-phase deltas are a group of smaller backstepping deltas formed during rapid Postglacial transgression after the LGM. Though smaller than the earlier delta complexes, formation of these systems under rapid rates of sea-level rise was in large part a consequence of a more humid climate and increased sediment discharge in the early Holocene. Together, delta sequences of the Texas shelf have formed under a variety of climatic and sea-level conditions, indicating the critical role that both of these forcings play.

Modeling studies

Quaternary climate change has been recognized as an important control on fluviodeltaic systems. However, it has been difficult to confidently link observed stratigraphic and sedimentological signatures to climatic forcings, given the strong overprinting of sea-level and marine processes on delta morphology. Such limits of field investigations are reflected in

Figure 8 Reconstructed late Quaternary history for the rivers and deltas of the Colorado (CR, CD), Brazos (BR, BD), Trinity (TR, TD), and Sabine (SR) fluviodeltaic systems on the northern Gulf of Mexico shelf. Phases of delta progradation, incision, and backstepping are shown with corresponding phases of sea level, and are also associated with periods of climate change and varying sediment discharge. Note larger-than-present deltaic lobes building on the mid-shelf during MIS-3 interstade, under apparently wetter climatic conditions. Climate and sea level are dominant controls on delta formation and have varied somewhat in-phase during the late Quaternary (see Figure 9), giving rise to complex fluviodeltaic responses. Reproduced from Anderson JB and Fillon RH (eds.) (2004) *Late Quaternary Stratigraphic Evolution of the Northern Gulf of Mexico Margin*, p. 314 Tulsa, OK: SEPM. Special Publication 79.

Figure 9 SPECMAP $\delta^{18}\text{O}$ and Milankovitch-tuned insolation records for the late Quaternary compiled by Imbrie, and Berger and Loutre, respectively. SPECMAP data represent a proxy for sea-level change and insolation serves as a coarse proxy for wetness in the subtropical (monsoon-influenced) Northern Hemisphere. Intended to show the general cophasing of peak insolation (generally wetter) with sea-level transgression, with the implied consequence of high sediment discharge corresponding with rapid sea-level rise. This pattern has been observed in the Yellow, Yangtze, and Ganges–Brahmaputra delta systems, west African rivers, and most likely in the Texas Gulf of Mexico rivers.

the relatively limited number of studies, many of which are discussed above. However, the exponential increase in computing power has allowed major advances to be made in the numerical modeling of fluviodeltaic systems. Several current models offer the opportunity to compare the consequences of forcing of fluvial delta systems by any combination of climate, eustasy, and tectonics, thereby helping elucidate the specific character of climate impacts on stratigraphic sequences (Overeem et al., 2005). This is especially relevant given that climate change and glacioeustasy are phased through most of the Quaternary (Figure 9), making it extremely difficult to derive unique interpretations of these forcings from field data alone.

One system that has been a focus of Quaternary response modeling is the Meuse river, which drains central Europe and discharges to the southern North Sea coast. Much of the research on this system during the past decade has had a focus on understanding the signatures of climate and eustasy contained in the late Quaternary stratigraphy and geomorphology (e.g., Veldkamp and Tebbens, 2001). Situated in the periglacial environments of northwest Europe during the Quaternary, climatically driven variations in the magnitude, timing, and nature of discharge appear to have played a role in shaping the fluviodeltaic system upstream of the hinge line. Terrace development in this river-dominated reach of the system is recognized as a primarily climate-controlled process through both modeling and field studies. However, the downstream impacts of such hydrological changes in the Meuse system appear to be insufficient to overcome the dominant influence of glacioeustasy during the Quaternary. Although there are likely to be impacts of climate in the delta, they remain indistinguishable at the resolution of current data and modeling capabilities.

Another system, the Niger delta, has been investigated using an industry-based stratigraphic model (van der Zwan, 2002). This investigation was aimed at testing the impact of presumed

Milankovitch-scale variations in sediment discharge over the Neogene. The orbitally linked forcing of regional climate and sediment occurred via global climate, insolation control of monsoon strength, and vegetation. Results suggest that sediment supply does change due to climatic variability at both large-scale (Ma) and Milankovitch-scale timeframes, and that there was a modest impact on stratigraphy. However, under icehouse conditions, fluctuations in climate-forced sediment supply were greatly overshadowed by rapid glacioeustatic sea-level change. These findings echo those of other modeling studies, in that climate is often found to be an important, but secondary, control on fluviodeltaic sequences. Furthermore, most modeling studies suggest that climatic signals preserved at the continental margin greatly lag the timing of the actual forcing in the fluvial catchment (e.g., Castellort and Van Den Driessche, 2003). This notion conflicts with recent field evidence from several of the subtropical rivers discussed above. Much of these discrepancies likely arise from our limited knowledge of appropriate input values for pre-Modern climate, riverine, and coastal conditions.

Geomagnetic Excursions and Secular Variations

Introduction

Earth is the only terrestrial planet to have a strong, largely dipolar magnetic field (i.e., a field similar to that of a bar magnet, with poles near both geographic poles). Since the time of William Gilbert (AD 1600), it has been widely acknowledged that the geomagnetic field has its origins within the Earth. Discovery of field variations through time dispelled the notion that the field could be due to a permanent magnetization. In the twentieth century, the idea of a dynamo operating in Earth's liquid iron-rich outer core became accepted. However, it has only been in the past two decades that computer simulations have demonstrated that such a dynamo mechanism can reproduce the observed features of the field (e.g., [Glatzmaier and Roberts, 1995](#)). The core fluid is in constant motion, driven by both thermal and compositional convection combined with Earth's rotation. Movement of the conducting fluid in a magnetic field causes electromagnetic induction of electric currents in the fluid. The currents themselves are a source of magnetic field, and under the right circumstances they can reinforce the original field, which results in a self-sustaining geodynamo ([Figure 1](#)).

Paleomagnetic evidence demonstrates that the geomagnetic field has existed from the Earth's early history (e.g., [Tarduno et al., 2006, 2010](#)) and that it is dynamic, with a broad spectrum of time variations. Calculations based on the attenuation of electromagnetic waves traveling through the mantle suggest that, for variations originating in the core to be observed at the surface of the Earth, they must have periods longer than about 1 year. Higher frequency geomagnetic variations are observed, but are external in origin (e.g., daily variations due to Earth's rotation, variations due to changes in solar activity, and interactions of the solar wind with the magnetic field). The sunspot cycle also contributes signals with periods of 11 and 22 years.

The range of field variability of relevance to this article originates in the geodynamo and occurs on timescales of years to millennia, and is known as 'geomagnetic secular variation.' Secular variation refers to the gradual changes in direction and intensity observed at all locations on Earth. The amplitude of the changes in field direction may be up to about 30°, and the field intensity can change by a factor of about 2. Occasionally, and apparently randomly, much larger changes occur, where the field intensity decreases drastically and the field direction undergoes large swings, after which the field settles back to its former state. This style of field behavior is referred to as a 'geomagnetic excursion.' Even more rarely the field destabilizes, in much the same manner as during an excursion, but instead of reverting to its former polarity state, the field recovers with the opposite polarity. In such cases, a polarity reversal has occurred. Geomagnetic field variability can be described by magnetohydrodynamic equations (e.g., [Glatzmaier and Roberts, 1995](#)); these equations do not depend on polarity. The paleomagnetic record indicates that, since the formation of Earth, the field has spent approximately equal amounts of time in the normal (i.e., like today) and reversed polarity states ([Merrill et al., 1998](#)). The longest geomagnetic polarity intervals are known as 'superchrons,' which represent periods of tens of millions of years when the geomagnetic field did not reverse polarity. Only two superchrons are well documented (the Permian or Kiaman reversed superchron and the Cretaceous normal superchron), while a third superchron has been postulated in the Ordovician ([Pavlov and Gallet, 2005](#)). Although the frequency of reversals has been highly variable throughout Earth's history, on average two or three reversals have occurred per million years throughout the Cenozoic. In this article, we describe how paleosecular variation (PSV), including changes in geomagnetic field intensity, geomagnetic excursions, and polarity reversals, can be used in Quaternary stratigraphy and geochronology.

Figure 1 Cut-away cartoon of Earth's interior with a view of the solid inner core and fluid outer core from which geomagnetic flux lines emerge. The helical lines represent flux emerging from columnar convection cells that occur within the larger scale flow of the outer core that drives the geodynamo. These cells transfer heat from the inner core–outer core boundary to the core–mantle boundary. The overall field is symmetrical about Earth's rotation axis. Over time, the field averages to that of a geocentric axial dipole.

Geomagnetism

The Present-Day Field

At most locations on Earth's surface, the compass needle does not point exactly to the north. The angle between true north and magnetic north (the direction of the compass needle) is known as the declination, while the angle of the magnetic field vector below the horizontal (or of a dip needle) is known as the inclination (**Figure 2(a)**). If the geomagnetic field were due simply to a geocentric axial dipole (GAD), then the declination would be 0 at all locations on the globe, and the inclination would depend only on latitude, with $\text{In}_{\text{GAD}} = \tan^{-1}(2 \tan \lambda)$. The field intensity is given by $\text{Int}_{\text{GAD}} = \frac{\mu_0 m}{4\pi r^3} (1 + 3 \sin^2 \lambda)^{1/2}$, where λ is the latitude, m is the dipole moment, r is Earth's radius and μ_0 is the permeability of free space (constant). While the geomagnetic field undergoes constant change, a snapshot of the field in AD 2010 is shown in **Figure 3**, where the declination, inclination, and intensity of the International Geomagnetic Reference Field (IGRF, International Association of Geomagnetism and Aeronomy, Working Group V-MOD, 2010) are contoured on a map of the world. The dominance of the GAD is seen by the fact that the intensity increases from between about 25 000 and 40 000 nT (nano-Tesla) around the equator to about 60 000 or 65 000 nT at high latitudes, and

that the inclination generally steepens from the equator toward the poles. However, in detail the field is clearly not axisymmetric. The best fitting dipole to the present-day field is tilted 10° with respect to Earth's rotation axis. The poles of this best fitting dipole, which are known as the 'geomagnetic poles,' are located at 80.0° N , 72.2° W , and at 80.0° S , 107.8° E . This dipole field accounts for about 90% of the total field. It is the residual 10%, which represents the non-dipole field, that accounts for the irregularities and anomalies seen in global plots of declination, inclination, and intensity (**Figure 3**). For example, the magnetic poles, the points at which the field is found to be vertical (inclination $= \pm 90^\circ$), do not coincide with the geomagnetic poles, but are displaced from them by amounts that depend on the local non-dipole field. The discrepancies are different in the two hemispheres, so that the magnetic poles are not antipodal. In 2010, the north magnetic pole was in northern Canada (85.0° N , 132.6° W), while the south magnetic pole lay to the south of Australia near the coast of Antarctica (64.4° S , 137.3° E). These are also the points from which declination contours radiate out (**Figure 3(a)**). Anomalous foci in inclination and intensity charts, such as the intensity minimum over South America and the southwest Atlantic (**Figure 3(c)**), and the steep inclination off South Africa (**Figure 3(b)**) are further evidence of the non-dipole field components, as also are the complexities of the declination chart (**Figure 3(a)**).

Figure 2 Definition of terms used to describe the geomagnetic field. (a) Three-axis coordinate system (north, east, and down), with definition of the declination and inclination of the geomagnetic field vector. Declination (D) is the angle of the horizontal component of the vector from true north, measured clockwise; inclination (I) is the angle of the vector from the horizontal (positive down); and intensity (B) is the length of the vector. Field measurements at any point can be described in terms of these components. (b) If the field is assumed to be due to a geocentric dipole, a magnetic measurement at any site on Earth's surface (S), with latitude, λ_s , and longitude, ϕ_s , will give rise to a virtual geomagnetic pole (VGP) that describes the geomagnetic field at that instant in time. The intensity of that field is given by the virtual dipole moment (VDM). (c) Definition of the virtual axial dipole moment (VADM), which is determined using the site co-latitude (θ_m) and the measured intensity (or paleointensity) at S . Equations are given for the VDM and VADM below (b) and (c), respectively. (b) and (c) are adapted from Tauxe L (2010) *Essentials of Paleomagnetism*. Berkeley, CA: University of California Press.

Further insight as to the cause of such features is gained by examining the field at the core–mantle boundary (CMB), which is calculated by the mathematical process of downward continuation (Figure 4). At the CMB, the highest field intensities are not at the poles, but occur at latitudes of between 70° and 80° . Furthermore, there are two high-intensity foci in each hemisphere. These four high-latitude ‘flux lobes’ are responsible for the predominantly dipolar field observed at the surface.

Virtual Geomagnetic Poles, Virtual Dipole Moments, and Virtual Axial Dipole Moments

The geomagnetic poles are the locations at which the axis of the best fitting dipole intersects Earth's surface. It is possible to take any single observation or paleomagnetic direction, and from it and the latitude and longitude, λ_s and ϕ_s , of the site from which it was obtained, calculate the poles of the geocentric tilted dipole, which would yield the observation. Such a pole is called a ‘virtual geomagnetic pole’ (VGP). The north VGP lies on the great circle defined by the observed declination D at a distance from the site corresponding to the ‘virtual’ or magnetic colatitude θ_m , which is calculated from the observed inclination I , as shown in Figure 2(b). Spherical trigonometric equations for calculating VGPs from λ_s , ϕ_s , D , and I are given in standard texts on paleomagnetism (e.g., Tauxe, 2010). If the paleointensity and inclination are known, it is possible to calculate the magnetic moment of the virtual dipole: the virtual dipole moment (VDM). If paleointensity is known, but a sample has not been oriented, the direction of the paleomagnetic field remains unknown. In such cases, the colatitude of the sampling site, θ_s , must be used instead of θ_m , and the result is known as a virtual axial dipole moment (VADM) as shown in Figure 2(c).

Conventionally, models of the field at the surface of the Earth are based on spherical harmonic analysis of the

geomagnetic potential. The potential is represented by a summation of a series of terms that generally decrease in magnitude and importance:

$$U = a \sum_{l=1}^{\infty} \sum_{m=0}^l \left(\frac{a}{r}\right)^{l+1} P_l^m(\cos \theta) (g_l^m \cos m\phi + h_l^m \sin m\phi)$$

where a is the radius of the Earth, r , θ , and ϕ are the radial distance from the pole, the colatitude and longitude of the site, respectively, P_l^m are associated Legendre polynomials, and g_l^m and h_l^m are known as the Gauss coefficients of the various surface harmonic components. The most widely used model of the geomagnetic field, the IGRF, is calculated every 5 years by finding the values of the Gauss coefficients that produce the best fit of such a model to observatory, satellite, and other data. In the most recent models, the coefficients are calculated to degree, l , and order, $m=13$. The first and largest term in the summation for the potential, $\frac{a^3}{r^2} g_1^0 \cos \theta$, represents a GAD. The next two terms, $\frac{a^3}{r^2} g_1^1 \cos \phi \sin \theta$ and $\frac{a^3}{r^2} h_1^1 \sin \phi \sin \theta$, represent dipoles in the equatorial plane along longitudes of zero and 90° , respectively. Together, these three terms represent the best fitting tilted dipole, and the orientation of this dipole (i.e., the geomagnetic pole positions) can be found from the coefficients g_1^0 , g_1^1 , and h_1^1 . Degree 2 terms correspond to quadrupole fields, degree 3 to octupole fields, etc., with each successive degree adding greater complexity to the model.

Secular Variation

Gauss pioneered a global network of geomagnetic observatories in the early nineteenth century. INTERMAGNET now

Figure 3 Global plots of the geomagnetic field at the surface of the Earth, calculated from the International Geomagnetic Reference Field for 2010. (a) Declination (in degrees; the green contour is the agonic (zero declination), with red and blue contours indicating eastward and westward declinations, respectively); (b) inclination (in degrees; the green contour is the magnetic equator (zero inclination), with red and blue contours indicating downward and upward inclinations, respectively). The contours are shown at 2° intervals in each case. (c) Intensity (in 1000 nT contour intervals). The intensity generally rises with increasing latitude. The maps are plotted in Mercator projections. From www.ngdc.noaa.org.

Figure 4 Vertical (or radial) magnetic field at the core–mantle boundary (CMB) in 1990, from the gufm1 model of Jackson et al. (2000). Blue represents flux entering the core and orange-red represents flux exiting from the core, while deeper colors indicate stronger field intensities. Note the two high-latitude flux concentrations in each hemisphere, and also the reverse polarity (blue) flux patch in the south Atlantic (after Jackson and Finlay (2007)). Note the much stronger field intensities at the CMB compared to Earth’s surface (cf. Figure 3(c)).

records and collates not only secular variation data, but also the shorter period variations of external origin. Amongst the longest records are the directional records from London, Paris, and Rome, which date back over 400 years (Figure 5(a)): variations at all three locations are clearly related, with the magnetic field vector describing what looks like three-quarters of a clockwise loop. However, the average inclination at Rome is some degrees lower than that at Paris, and at Paris the average inclination is slightly shallower than that at London. This again is evidence of the dominance of the main dipole field for which inclination is latitude-dependent. A much shorter record from a Southern Hemisphere site, Melbourne (Figure 5(b)), has no clear correlation with European records for the same period. This indicates that the changes are largely related to features of the non-dipole field, which are coherent over regions of continental extent only. Early examinations of such historical records, particularly of those from Europe and North America, led to the suggestion of westward-drifting eddy-like features in Earth’s outer core. Bullard et al. (1950) estimated an average drift rate of 0.18° per year for the Atlantic region between 1907 and 1945. This westward drift is seen clearly in animated global charts of declination changes over the past 400 years (Jackson et al., 2000; <http://jupiter.ethz.ch/~cfinlay/gufm1.html>). However, such animations also demonstrate that westward drift is not ubiquitous. Over other areas of the globe, features grow and decay without drifting significantly, or they even drift eastward, while there is little secular variation over the Pacific hemisphere.

From the late eighteenth century, scientists and mariners began to obtain relative measures of field intensity by measuring the period of oscillation of a dip needle. It was not until 1832, however, that Gauss devised a method of calibrating measurements to give absolute values of field intensity. At most, but not all, locations on Earth, the field intensity has decreased significantly over the past two centuries, although the decrease has not been steady or uniform.

Paleomagnetism

How Rocks Become Magnetized

Detailed historical records of geomagnetic secular variation are available only for the last 400 years (Jackson et al., 2000). In order to retrieve information about variations of the magnetic field beyond this period of historical observations, it is necessary to use paleomagnetic techniques. Use of paleomagnetism requires an understanding of how geological materials record geomagnetic information. The stability of the remanent magnetization in question is largely dependent on the grain size of the magnetic particles. Ideal magnetic recording occurs in particles that have uniform magnetization. Such particles have a magnetic single-domain (SD) state. In magnetite, which is the most common terrestrial ferrimagnetic rock-forming mineral, the particle size range for stable SD behavior is 30–80 nm (Tauxe, 2010). Magnetizations do not remain stable forever: they decay over time. However, for stable SD particles, the so-called relaxation time exceeds the age of the Earth if the rock containing the SD particles remains at ambient temperatures. It is this high magnetic recording fidelity of SD grains that provides the basis for the usefulness of paleomagnetism in Earth science. Different materials acquire a long-lived, or remanent, magnetization through different mechanisms. In Quaternary geology, many materials can be analyzed paleomagnetically; therefore it is important to consider the main mechanisms by which remanent magnetizations are acquired.

A thermoremanent magnetization (TRM) is acquired as a material cools from high temperatures. A TRM is typically responsible for the magnetization of igneous rocks, rocks that have been in contact with igneous bodies (baked margins) or that have been heated by burial, or archaeological artifacts that have been subjected to firing (e.g., pottery). When a ferro or ferrimagnetic material is heated above its Curie temperature, increased thermal energy causes the magnetic moments of

Figure 5 Historical records of the direction of the geomagnetic field at (a) London, Paris, and Rome for the past 400 years, and at (b) Melbourne since 1858. Inclination is plotted against declination, so each curve traces the movement of the tip of the magnetic vector when viewed along the vector direction. Similar clockwise loops for London, Paris, and Rome are indicative of regionally coherent secular variation. The secular variation pattern in Melbourne is completely different from that in Europe. During the twentieth century, increased electromagnetic interference from cultural sources has meant that observatories in all cities shown have been moved to more magnetically quiet locations. Each record is therefore a composite from different observatories, adjusted to a common location.

individual atoms to randomize (Figure 6(a)). As the material is cooled through the Curie temperature, the interatomic distance decreases and the resulting magnetic exchange interaction causes spontaneous alignment of atomic magnetic moments. This enables TRM acquisition, with the rock recording an overall magnetization that is parallel to the ambient geomagnetic field direction (Figure 6(b)). A TRM is generally

highly stable, and fine-grained volcanic rocks often provide ideal paleomagnetic records.

When igneous rocks are eroded, magnetic minerals are transported along with other mineral detritus until they are eventually deposited as sediment. During deposition in a quiet environment, magnetic particles will have a torque exerted on them by the geomagnetic field, which causes

Figure 6 Illustration of how rocks acquire a remanent magnetization. (a) When lava flows are hot (i.e., above the Curie or blocking temperatures of the magnetic minerals in the lava), thermal energy exceeds any atomic magnetic exchange energy and the magnetic moments are randomized. (b) When the lava cools through the Curie and blocking temperatures, a thermoremanent magnetization (TRM) is acquired, which is aligned parallel to the ambient geomagnetic field. (c) When magnetic particles are eroded from a source rock and are deposited as a sediment, the particles may align with the geomagnetic field to give rise to a depositional remanent magnetization (DRM). If the sediment is remobilized (e.g., by bioturbation), high water contents may allow the magnetic particles to realign with the geomagnetic field via the torque exerted on such particles by the field, which gives rise to a postdepositional remanent magnetization (PDRM). Figures (a) and (b) are after Marshak (2008); Figure (c) is modified after Tauxe and Yamazaki (2007).

their magnetic moments to rotate toward the ambient field direction (**Figure 6(c)**). Such a magnetization is referred to as a 'depositional remanent magnetization' (DRM). If deposition occurs in the presence of even a minor hydro/aerodynamic disturbance, the perturbation will exceed the geomagnetic torque and magnetic particles will not be ideally aligned with the geomagnetic field (e.g., [Heslop, 2007](#)). Particles can also rotate when they settle onto the sedimentary substrate, or be flattened into the bedding plane by compaction, or can be disrupted and moved by bioturbation. The low likelihood that a pure DRM will survive physical disturbance during deposition, bioturbation, or Brownian motion can be overcome by invoking a postdepositional remanent magnetization (PDRM). PDRM acquisition is argued to occur within the unconsolidated uppermost sediments in which water contents are high. In this environment, the geomagnetic field can exert a torque on magnetic particles after their last disturbance. This realigns the particles with their magnetic moments parallel to the geomagnetic field and imparts a PDRM, which becomes locked in at some depth below the sediment–water interface (**Figure 6(c)**). This depth can vary and is an elusive parameter that is rarely well constrained. It is usually assumed to be less than 20 cm (e.g., [Roberts and Winklhofer, 2004](#)).

In some environments, chemical changes give rise to the growth of magnetic minerals that record a chemical remanent magnetization (CRM). Under oxic diagenetic conditions, hematite can form after deposition and give rise to a CRM when grains grow through the critical SD blocking volume. The origin and timing of magnetization acquisition in red sediments can be uncertain and has been debated intensely (e.g., [Larson and Walker, 1975](#); [Tauxe and Kent, 1984](#)). Under anoxic diagenetic conditions, postdepositional growth of the magnetic iron sulfide, greigite, can lead to either faithful or complex paleomagnetic records depending on the timing of CRM acquisition (e.g., [Roberts et al., 2011](#)). If monoclinic pyrrhotite forms within sediments, it is likely to cause a later diagenetic remagnetization (e.g., [Hornig and Roberts, 2006](#)). CRM acquisition therefore causes complications, which require considerable care when interpreting paleomagnetic records.

Assessing the Reliability of Paleomagnetic Data

When using paleomagnetism to date Quaternary rocks and sediments, the most desirable magnetizations that are likely to give rise to high-fidelity recording of the geomagnetic field are a TRM or a DRM/PDRM. After sampling, it is necessary to subject samples to rigorous laboratory demagnetization procedures to assess the stability of the recorded magnetizations before any interpretation can be made in terms of field behavior or chronology. The most common laboratory procedures involve a progressive, stepwise alternating field or thermal demagnetization. The efficacy of one technique compared to the other depends largely on the nature of the sample, the magnetic minerals present, and the range of grain sizes in which the magnetic minerals occur. In many cases, it is important to undertake a pilot study to determine the most effective technique to use. After completion of stepwise demagnetization, the paleomagnetic data can be inspected using vector demagnetization diagrams, which enable identification of secondary remanence components and the most stable

'characteristic' remanent magnetization (ChRM) component. Use of the word 'characteristic' avoids premature linking of the documented magnetization to an interpretation of whether it is primary or not. Where possible, it is highly desirable to use a range of paleomagnetic field tests to assess whether the recorded ChRM is an ancient or later magnetization. These tests include the fold test, the conglomerate test, the baked contact test, and the reversals test. For details of demagnetization procedures and field tests, the reader is referred to a recent comprehensive online text ([Tauxe, 2010](#)). In many cases, however, investigated rocks or sediments may not be folded, and they may not contain intraformational conglomerates, baked contacts, or geomagnetic reversals. In such cases, one is more dependent on the coherence of the recorded paleomagnetic signal and how well it compares with other well-documented geomagnetic information, such as continuous records of PSV or relative geomagnetic paleointensity. It is important to emphasize that successful interpretation of paleomagnetic data in terms of geochronology depends on rigorous field and laboratory work, and that unidentified problems associated with CRM acquisition, failure to identify a robust ChRM through detailed stepwise demagnetization, physical disturbance of the paleomagnetic record, or other issues may lead to difficulties that preclude geochronological interpretation.

While TRM and DRM/PDRM might be the most useful remanence acquisition mechanisms for geochronological applications, it is also useful to consider their limitations. For example, while a TRM is usually considered to be the ideal type of magnetic remanence, even volcanoes with the most frequent eruptions will not provide the continuous paleomagnetic records needed to document a wide spectrum of field behavior. Significant time gaps between eruptions can also complicate chronological interpretation. In contrast, sedimentary sequences can provide virtually continuous records of field variability. However, a DRM is not an efficient recorder of paleomagnetic information, and inclination errors, which represent significant divergences from the ambient geomagnetic field direction, are commonly associated with DRM acquisition (e.g., [King, 1955](#); [Tauxe, 2005](#)). This can be especially important in hematite-bearing sediments (e.g., [Tauxe and Kent, 1984](#)) and in eolian sediments (e.g., [Zhao and Roberts, 2010](#)). A PDRM might be considered an improvement on a pure DRM because it provides an opportunity for magnetic particles to become reoriented with the ambient geomagnetic field shortly after deposition. However, it is likely that a PDRM is locked in over a depth range rather than at one specific and narrow horizon, which will cause smoothing of the paleomagnetic signal (e.g., [Verosub, 1977](#)). This smoothing, at minimum, serves as a low-pass filter, so that the highest frequency field variations are removed from the paleomagnetic record (e.g., [Roberts and Winklhofer, 2004](#)). Despite these complexities and limitations, paleomagnetism provides the principal means of reconstructing geomagnetic field variations beyond the last 400 years, and can be a robust technique for Quaternary geochronology.

Determining Geomagnetic Field Intensity

The geomagnetic field is a vector, with both a direction and intensity (**Figure 2(a)**). Many paleomagnetic studies simply use the field direction to obtain, for example, a magnetic

polarity stratigraphy or for tectonic reconstructions. But the geomagnetic field intensity also contains valuable information concerning field variability that is relevant to Quaternary stratigraphy.

Volcanic rocks and fired archaeological artifacts provide the most reliable records of geomagnetic field intensity. When a TRM is acquired during cooling, the strength of the TRM is proportional to the ancient field intensity (B_{anc}). It is necessary to undertake a series of laboratory experiments to determine the proportionality factor between the TRM intensity and the absolute geomagnetic intensity (Thellier and Thellier, 1959). A second TRM is imparted in the laboratory by heating and cooling the sample in a known applied laboratory field (B_{lab}). The paleofield intensity is then determined from $B_{anc} = (TRM_{anc}/TRM_{lab})B_{lab}$. Absolute paleointensities have been widely used to date archaeological materials via comparison with regional archaeomagnetic master curves (see below). Time series of intensity variations from volcanic rocks are also useful for understanding geomagnetic field variability over longer timescales. However, as stated previously, volcanic records are not continuous and it is desirable to obtain continuous records of geomagnetic paleointensity variations for Quaternary dating. Sedimentary records provide the greatest potential for obtaining continuous paleointensity records, but they do not allow determination of the absolute strength of the ancient geomagnetic field.

The relationship between geomagnetic field intensity and DRM or PDRM intensity is much more complex than for rocks that carry a TRM. The DRM intensity is affected not only by the strength of the ambient magnetic field and the concentration of magnetic minerals but also by the nature of the magnetic mineral that records the paleomagnetic signal, its grain size, and the mechanism by which the magnetization was acquired. The effects of most of these variables can be offset by normalizing the natural remanent magnetization (NRM) of sedimentary samples by an artificial laboratory-induced magnetization and by imposing strict rock magnetic selection criteria. These criteria require that magnetite must be the only magnetic mineral present and that it occurs within a narrow grain size range with a small range between its maximum and minimum concentrations (cf. Tauxe, 1993). By applying these strict selection criteria, it has been demonstrated that the geomagnetic field varies in a globally coherent manner on millennial timescales (and on smaller timescales where such variations are recorded in high-resolution datasets, e.g., St-Onge et al., 2003) and that it is possible to use these variations to date sedimentary sequences (e.g., Channell et al., 2008; Hornig et al., 2003; Laj et al., 2000; Stoner et al., 2002; Tauxe and Yamazaki, 2007; Valet et al., 2005; Yamazaki and Oda, 2005; Ziegler et al., 2011). The potential for paleointensity-assisted chronology in Quaternary sediments is explored in more detail below (section 'Relative Geomagnetic Paleointensity Variations').

Paleosecular Variation Records

Secular Variation Recorded in Archaeological Artifacts and Lava Flows

As a result of the meticulous work of many research groups over the past several decades, detailed records of changes in field direction and intensity have been compiled from

archaeomagnetic studies. These records cover only parts of the world and time periods during which pottery was made; few records extend back before 1000 BC. Some of the most detailed, best resolved records come from Europe – a selection of which are shown in Figure 7. Retrieval of the direction of the paleomagnetic field requires knowledge of the orientation of the artifact at the time of its firing and subsequent cooling. For incomplete pottery fragments, the orientation is often not available. In such cases, only the paleointensity can be determined. Even with complete objects, the orientation may be only partially known; for example, it may be known that a pot was fired upright or upside down, but its azimuthal orientation may be uncertain. Hence, inclination, but not declination, might be retrievable. Each archaeomagnetic determination involves a discrete object, therefore each artifact must be dated individually, and each age estimate carries its own uncertainty. Various dating methods are commonly used, ranging from primary methods such as radiocarbon and thermoluminescence dating of contextual material to secondary methods that include historical records of site occupation, pottery design, etc. Each dating method has its own limitations and uncertainties. Regional master curves are compiled by combining all available data that meet carefully chosen reliability criteria from within a certain region. For example, the Western Europe curves of Gallet et al. (2002) include data from France, Great Britain, and Southern Italy, while the curve of Schnepf and Lanos (2006) contains data from within a 500-km radius of the town of Radstadt, Austria (Figure 7). Individual declinations and inclinations are 'reduced' to a common location, Paris and Radstadt in the two examples of Figure 7, to take account of geographic spread. This is usually done by calculating a VGP position (see separate text box), and then calculating the expected direction (D and I) at the common location. Also shown in Figure 7 are lake sediment data (see below) from Great Britain (Turner and Thompson, 1981, 1982), which have also been reduced to the latitude and longitude of Paris. The data agree well (Figure 7), which indicates that these independent datasets record a common underlying geomagnetic signal. Algorithms are now available that enable statistical comparison of the paleomagnetic direction and intensity of an artifact of unknown age with these regional archaeomagnetic master curves of declination, inclination, and intensity (Lanos et al., 2005; Schnepf and Lanos, 2006).

An alternative recently developed approach involves production of regional field models from archaeomagnetic data. The data are not transformed to a common location, but are fitted to a series of mathematical functions in a manner similar to the global models based on spherical harmonic functions (see Section 'The Present-Day Field'). At least two different types of functions are currently being investigated – spherical cap harmonic functions (Haines, 1985; Pavón-Carrasco et al., 2009, 2010; Thébaud et al., 2006) and Slepian functions (Dahlen and Simons, 2008). In principle, once such a model has been calculated for a region, and regularized over time, it is then possible to calculate a secular variation curve for any chosen location within the region. In Figure 7, declination and inclination curves for the latitude and longitude of Paris, which are calculated from the SCHA.DIF.3K spherical cap harmonic model of Pavón-Carrasco et al. (2009) for Western Europe, are also shown. Finally, much smoother curves are obtained from the global CALS3k model (Korte et al., 2009),

Figure 7 Archaeomagnetic secular variation records from Europe. (a, b) Declination and inclination records from France. Each point represents an average over a 160-year window, calculated at 50-year intervals (error bars represent 95% confidence intervals associated with the archaeomagnetic directions). All directions were referred to Paris using an intermediate VGP transformation (open symbols are from Bucur (1994) and closed symbols are from Gallet et al. (2002)). The solid red lines denote the British lake sediment record of Turner and Thompson (1981, 1982), which is also referred to the latitude and longitude of Paris (after Gallet et al. (2002)). Blue and yellow lines represent curves from the regional and global models of Pavón-Carrasco et al. (2009) and Korte et al. (2009), respectively. (c) Archaeomagnetic paleointensity measurements from France, Spain, Norway, and Denmark, all referred to the latitude of Paris, compiled by Gómez-Paccard et al. (2008). The solid red line and shading represent the mean and 95% confidence interval. The blue and yellow lines are as in (a) and (b). (d, e) Archaeomagnetic declination and inclination master curves for Austria with mean and 95% confidence curves obtained by Bayesian modeling. Compiled from data within a 500-km radius of the town of Radstadt, Austria (Schnepp and Lanos, 2006).

which is based on spherical harmonic analysis of worldwide data. Such models are useful for predicting secular variation curves from regions where data are sparse but are not yet well enough resolved to provide a high-resolution dating tool.

Secular Variation Recorded in Lake and Marine Sediments

Development of purpose-designed piston corers has enabled collection of long lake and marine sediment cores without disturbing, compressing, or twisting the recovered sediments. Since the 1970s and 1980s, detailed PSV records have been obtained as a result of continuous subsampling of such cores, followed by detailed paleomagnetic analysis. Several cores are usually taken from a lake, and can be correlated using magnetic susceptibility signatures and lithological markers. The respective PSV records can then be stacked or averaged to provide a local or regional PSV master curve. Age control is usually provided by radiocarbon dating of organic material, palynology, and/or identification of known tephra. Examples of lacustrine regional PSV records include the British record of Turner and Thompson (1981, 1982), the Southeast Australian record of Barton and McElhinny (1981, 1982), the Minnesota record of Lund and Banerjee (1985), the eastern United States stack of King and Peck (2001), and the Fennoscandian stack of Snowball et al. (2007), all of which cover most of the Holocene. In periods where the records overlap, the best records compare extremely well with archaeomagnetic records from the same region. Several lacustrine and marine PSV records that extend from the west coast of North America to

Europe are shown in Figure 8. Correlation, particularly of declination records over the past 3000–4000 years, is striking. There is, however, no obvious east–west time lag, as would be expected if westward drift was a significant feature of the secular variation. Especially prominent in nearly all the records is the large eastward swing in declination at about 2700 BP, labeled by Turner and Thompson (1981) as ‘f.’ This coincides with relatively high inclinations, which makes the overall direction particularly distinctive for dating purposes. Swing ‘f’ is not well represented in either the global CALS7K model (Korte and Constable, 2005), which was compiled from archaeomagnetic and lake sediment records, or in the European regional SCHA8K model (Pavón-Carrasco et al., 2010), possibly because both models are restricted to low degree and order functions. The current generation of global models is also compromised by data scarcity from the Southern Hemisphere, particularly the South and Southwest Pacific. Even though much work is needed to retrieve high-resolution PSV records in such regions to constrain and improve global models, comparison with regional PSV master curves provides an effective means of dating Holocene sediments at decadal to millennial-scale resolution.

Long-Timescale Relative Paleointensity Variations

Since the early 1990s, much effort has gone into obtaining records of relative geomagnetic paleointensity spanning tens or hundreds of thousands of years. Globally coherent

Figure 8 Comparison of Northern Hemisphere Holocene PSV records. Declinations are plotted on the left and inclination records are plotted on the right (see Barletta et al. (2010) for sources of each record). The records demonstrate the use of PSV features for wide-scale regional correlation. The British lake sediment PSV record of Turner and Thompson (1981) is shown above the other records, with the global CALS7K (red) and regional SCHA8K (blue) model curves superimposed (calculated for the latitude and longitude of Loch Lomond). Except for the British record, the declinations have been standardized by subtracting the arithmetic mean declination for each record from each measured declination, and then dividing by the standard deviation. Adapted from Figure 7 of Barletta F, St-Onge G, Stoner JS, Lajeunesse P, Locat J (2010) A high-resolution Holocene paleomagnetic secular variation and relative paleointensity stack from eastern Canada. *Earth and Planetary Science Letters* 298: 162–174.

paleointensity variations are well represented in a series of stacked regional (Laj et al., 2000; Stoner et al., 2002; Yamazaki and Oda, 2005) and global (Tauxe and Yamazaki, 2007; Valet et al., 2005; Ziegler et al., 2011) records (Figure 9). The robustness of these paleointensity stacks is improving with time, and we now have paleointensity time series that collectively span the Quaternary (Channell et al., 2008; Horng et al., 2003; Tauxe and Yamazaki, 2007; Valet et al., 2005; Yamazaki and Oda, 2005; Ziegler et al., 2011). While it is always desirable to have an independent chronology, relative paleointensity records are now recognized to be useful for developing age models for sedimentary sequences. Many paleoceanographic proxies that are used to develop age models for marine sediments are dependent on seawater chemistry, and millennial-scale synchronization of such records can be complex (e.g., Skinner and Shackleton, 2005). In contrast, long-period geomagnetic variations provide a globally synchronous geophysical parameter that is independent of seawater chemistry, which can potentially be used to develop independent millennial-scale chronologies. Continuous relative paleointensity variations also provide a context within which geomagnetic excursions can be more robustly correlated from site to site. There is therefore considerable potential for using paleointensity variations in chronostratigraphy. Nevertheless, as stated previously, magnetically uniform sediments are needed to satisfy strict selection criteria for relative paleointensity studies and there are many environments and sediment types from which it is not possible to obtain high-quality relative paleointensity data.

Geomagnetic Excursions

A geomagnetic excursion is usually defined as a deviation of VGPs by more than 40–45° from the geographic pole (Merrill and McFadden, 1994) or as a deviation of VGPs away from the normal range of geomagnetic secular variation (Vandamme, 1994). Using geomagnetic excursions for the purposes of stratigraphic correlation assumes that certain key questions are answered. For example, are excursions local or global in extent? Do they represent dominantly dipolar or non-dipolar field variations? Are they rare or frequent? Do they exhibit characteristic styles of field behavior that enable unique identification of one particular excursion compared to another? Are they related to geomagnetic secular variation or are they aborted polarity reversals? Progress in answering these questions has recently been summarized by Roberts (2008), but they remain subjects of intensive research to which complete answers are still not available. A repeated problem in using Quaternary excursions for stratigraphic dating is that anomalous data have often been emphasized at the expense of less interesting but more robust data, which, combined with poor chronological constraints, means that dubious ‘excursion’ records have often been used to estimate the age of a sedimentary sequence. This has led to a ‘reinforcement syndrome’ (Thompson and Berglund, 1976) that complicates geomagnetic excursion research and that has wreaked widespread chronostratigraphic havoc in Quaternary research. In providing reasons for why excursions should not be used for stratigraphic correlation, Merrill and McFadden (2005) argued that excursions are not

global phenomena, and therefore that correlation of excursions should be limited to locations separated by angular distances of less than 30° on Earth’s surface. However, detailed high-resolution records obtained for the best studied excursions indicate that at least some excursions are recorded on a global scale (Laj et al., 2006). Lack of recording of excursions in many high-resolution sedimentary paleomagnetic records could result from smoothing associated with PDRM acquisition (Roberts and Winklhofer, 2004). Issues associated with potential PDRM filtering need to be borne in mind among other pitfalls of using excursions for stratigraphic correlation.

Only two geomagnetic excursions, the Laschamp (~40 ka) and Iceland Basin excursions (~190 ka), have been studied in sufficient resolution to provide any idea of whether excursions exhibit characteristic transitional field behavior (Laj et al., 2006). Similarities in the excursive VGP pathways for these two excursions mean that excursions are unlikely to provide a unique basis for correlation based on field behavior. Therefore, avoiding spurious reinforcement of anomalous paleomagnetic data requires that excursion records should be used with extreme caution in Quaternary geochronology without additional high-quality chronostratigraphic data.

With the above warnings in mind, it is worth considering the evidence for different excursions when they can be placed within a precise chronostratigraphic framework. As outlined by Roberts (2008), high-resolution paleomagnetic (including relative paleointensity) and $\delta^{18}\text{O}$ analysis of marine sediments and radioisotopic dating of volcanic rocks over the last decade have verified the precise age of some excursions (e.g., Mono Lake, Laschamp). New excursions have been identified (e.g., Iceland Basin, Bjorn, Gardar), and poorly dated excursions have been precisely dated (e.g., Pringle Falls, West Eifel; Singer et al. (2008a,b)). Unverified excursions have been discredited (e.g., Lake Mungo, Gothenburg, Biwa, Jamaica), and others remain to be fully validated and accepted (e.g., Norwegian-Greenland Sea, Calabrian Ridge 0, 1, 2, and 3). Following the critical reassessment of the evidence for documented excursions by Laj and Channell (2007), seven Brunhes Chron excursions are shown as validated in Figure 9, with six others indicated as ‘possible.’ This revised excursion catalog provides an update to the compilations of Langereis et al. (1997) and Lund et al. (2001). All ‘validated’ and ‘possible’ excursions are associated with paleointensity minima (Figure 9), as are all full polarity reversals. The geomagnetic field is evidently dynamic with constantly changing paleointensity and abundant collapses in field intensity (Figure 9). Excursions occur during such periods of weak paleointensity, and it is now clear that excursions are an intrinsic and frequent component of field behavior. A high-quality excursion catalog is likely to grow in future as detailed studies are performed for progressively older time intervals. We emphasize that excursions are best used in Quaternary stratigraphy when they are well constrained by independent chronological data, including continuous relative paleointensity records.

Geomagnetic Reversals

Of the range of documented geomagnetic field variations, polarity reversals are the most spectacular. With recent revision of

Figure 9 Geomagnetic polarity and relative paleointensity variations and excursions through the Quaternary. Polarity is indicated at the top of the figure, with black=normal and white=reversed polarity. Validated excursions are indicated along with their respective ages above the polarity log in italics, with ‘possible’ excursions that have yet to be fully validated indicated in red below the polarity log (from [Laj and Channell, 2007](#)). Each polarity reversal and excursion coincides with a paleointensity minimum. The relative paleointensity record of [Horng et al. \(2003\)](#) is used for the last 2 My because it has a high-quality, astronomically tuned chronology, and the record of Yamazaki and Oda (2005) is used from 3 to 2 Ma because it is one of few records that span this time interval. The climatic context of the geomagnetic variations is illustrated using the global stacked benthic $\delta^{18}\text{O}$ record of [Lisiecki and Raymo \(2005\)](#); oxygen isotope stages mentioned in the text are numbered (19 and 31).

the definition of the Quaternary Period, the boundary between the Neogene and Quaternary is closely associated with the Gauss–Matuyama reversal (Head et al., 2008; Ogg and Pillans, 2008), which makes paleomagnetic dating fundamentally important in defining the Quaternary (Figure 9). Compared to the other types of geomagnetic field variability discussed above, the number of full polarity reversals that have occurred during the Quaternary is small. Paleointensity-assisted chronology is therefore a welcome development for extending the usefulness of paleomagnetism in high-resolution Quaternary dating. Nevertheless, geomagnetic reversal stratigraphy is still extremely useful in Quaternary geochronology. For example, identification of the last reversal, namely, the Matuyama–Brunhes (M/B) boundary, provides an important marker in many studies including those concerning the presence of ancient humans (e.g., Muttoni et al., 2011; Parfitt et al., 2010). The M/B boundary occurred during a warm interglacial period, namely, marine isotope stage (MIS) 19 (e.g., Tauxe et al., 1996), which is increasingly being studied as a potential analog for future climate change (e.g., Tzedakis et al., 2009). The period between the Jaramillo subchron and the early Brunhes Chron is important for understanding the mid-Pleistocene transition (Figure 9) in which climate variability changed from low-amplitude orbital-obliquity-dominated (41 ka) to high-amplitude eccentricity-dominated (100-ka) cyclicity (e.g., Mudelsee and Schulz, 1997). Likewise, identification of the lower Jaramillo reversal provides an indication of the presence of MIS 31 (Figure 9), which was one of the warmest Quaternary interglacials and is another potential analog for future climate change (e.g., Scherer et al., 2008). The Gauss–Matuyama boundary coincided with intensification of Northern Hemisphere glaciation and is now fundamental to defining the Quaternary. Development of the astronomically calibrated geomagnetic polarity timescale means that identification of a polarity reversal provides a time marker that is precise to within 3 ka (Lourens et al., 2004). Thus, while reversal frequency is not high in the Quaternary, the globally synchronous nature of polarity reversals and the high chronological precision afforded by identification of reversals make magnetic polarity stratigraphy extremely powerful for addressing many problems in Quaternary science.

Paleomagnetic Dating in Quaternary Stratigraphy

High-fidelity paleomagnetic recording is most likely to occur in rocks and sediments that are magnetically dominated by SD or slightly coarser magnetic particles. Such particles are most often found in fine-grained volcanic rocks and in fine-grained organic-carbon-poor sediments. As summarized previously, a range of geomagnetic phenomena can be used to date Quaternary rocks and sediments. These phenomena are applicable to different age intervals and have variable requirements in terms of the types of materials from which suitable paleomagnetic records can be obtained.

Paleosecular Variation

Short-period secular variations can provide decadal to centennial age resolution. Achievement of this level of resolution is limited

to the Holocene, which is the only time interval for which we have high-quality regional PSV master curves. PSV studies are also best undertaken on continuously and rapidly deposited fine-grained lithogenic sediments. Extending such detailed records further back in time is often difficult because of changes in sedimentation in many depositional environments at the Last Glacial Maximum. Nevertheless, development of longer term PSV master curves represents an important target for future work.

Relative Geomagnetic Paleointensity

Millennial-scale geomagnetic variability provides a powerful global-scale phenomenon that can be used to develop paleointensity-assisted chronologies. Significant recent developments now enable the use of relative geomagnetic paleointensity throughout the Quaternary (e.g., Figure 9). Such records can only be obtained from fine-grained sediments that pass strict criteria for magnetic uniformity (e.g., Tauxe, 1993), which limits the applicability of this technique. Nevertheless, while it is ideal to constrain relative paleointensity chronologies with other high-quality chronostratigraphic information, paleointensity has been used as a principal dating technique in high-latitude marine sediments that are corrosive to calcium carbonate and which preclude determination of $\delta^{18}\text{O}$ -based chronologies (e.g., Sagnotti et al., 2001). Relative geomagnetic paleointensity analysis therefore represents an important advance in the paleomagnetic armory for dating Quaternary rocks and sediments.

Geomagnetic Excursions

Large-amplitude, short-period geomagnetic features such as excursions are among the most problematic geomagnetic phenomena for use in Quaternary stratigraphy. Without precise independent chronological constraints, such as a well-constrained relative paleointensity context, use of excursions to date sediments is an extremely precarious activity. For example, glacial deformation of sediments can produce anomalous paleomagnetic directions, which could be interpreted as a geomagnetic excursion without rigorous field and independent chronological constraints (e.g., Verosub, 1975). Excursions are among the most abused geomagnetic phenomena in Quaternary stratigraphy. We therefore urge extreme caution when interpreting anomalous paleomagnetic directions in terms of geomagnetic excursions. Lack of unique known geomagnetic field behavior that can be related to specific excursions leads us to recommend that they should not be used as a basis for dating sediments.

Geomagnetic Reversals

Unambiguous identification of a geomagnetic reversal provides a globally isochronous marker horizon. Magnetic reversals are therefore extremely powerful for dating. Many types of rocks and sediments, even those that are not ideal for studies of PSV or paleointensity, provide information about paleomagnetic polarity, which means that reversals have been used successfully in a wide range of Quaternary studies. However, the relatively low reversal frequency in the Quaternary (12 reversals in the last 2.59 Ma; Figure 9) means that

paleomagnetic reversal stratigraphy is a low-resolution dating tool. For many purposes, however, magnetic reversal stratigraphy can help to address important questions.

Conclusions

Diverse geological materials can be subjected to paleomagnetic investigation in Quaternary studies. Not all materials are suitable for paleomagnetic investigation, but careful study of appropriate materials can enable paleomagnetic documentation of decadal to millennial-scale geomagnetic variations, which have considerable potential for providing precise age constraints. These geomagnetic phenomena range from PSV (which is most useful in the Holocene), relative paleointensity variations (which are useful throughout the Quaternary), geomagnetic excursions (which are generally not useful for stratigraphic correlation unless accompanied by precise additional chronological constraints), and polarity reversals (which are useful between 2.59 and 0.78 Ma). A powerful aspect of using these geomagnetic variations is that they can generally provide chronological precision to within a few ka (or better in some instances). Paleomagnetic analysis therefore provides a key dating technique in Quaternary science.

“Life is not an external or accidental phenomenon of the Earth’s crust. It is closely bound to the structure of the crust, forms part of its mechanism, and fulfils functions of prime importance to the existence of this mechanism. Without life, the crustal mechanism would not exist.”

(Vladimir Vernadsky, *The Biosphere*, 1926)

Introduction

A current paradigm in plant ecology is that the geographical distribution of dominant land plant forms is mainly controlled by climate (Woodward, 1987). If climate alters, vegetation cover closely follows the change in the climatic patterns. In turn, changes in spatial distribution and composition of terrestrial vegetation (as well as marine biology) alter climate through modifications of heat and water fluxes, atmospheric gases, and aerosol composition. Biogeochemical and biophysical mechanisms form numerous feedbacks between biosphere and climate that were active during Earth’s geological past and continue to operate at present.

Quaternary changes in terrestrial and marine biology are recorded in sediments around the planet. A picture emerging from pollen and macrofossil reconstructions is that forest cover was greatly reduced at the maxima of Pleistocene glaciations, while during the warmest phases of interglacials, expanded forests covered almost a half of the ice-free land surface. These dramatic changes in forest cover had several important implications for climate dynamics. Coldness and aridity of glacial climates were amplified by land-cover changes through increase in land-surface albedo (the fraction of solar radiation reflected back into the atmosphere), decrease in transpiration, and enhanced dust formation on exposed bare ground.

Fewer forests and lower productivity during glacial periods should have led to reduced terrestrial biomass and soil carbon

storages, and the consequent release of carbon dioxide (CO₂) to the atmosphere that slightly offset the radiative cooling. This stabilizing effect is invisible in ice-core CO₂ records due to counteracting amplifying feedback between temperature and greenhouse gases that led to the lowering of atmospheric CO₂ levels during glacial periods. One of the hypothesized biological mechanisms that receive some support from proxy data is an iron fertilization effect on glacial marine productivity due to increased levels of dust depositions. The role of slow biogeochemical processes such as coral reef growth and continental weathering in atmospheric CO₂ dynamics is not yet well constrained.

Main Mechanisms of Climate–Biosphere Interaction

Photosynthesis

The process of photosynthesis that has existed on Earth for more than 3 billion years is a focal point of climate–biosphere interaction. Terrestrial plants capture CO₂ from the atmosphere while marine phytoplanktons take up carbon from seawater, which exchanges CO₂ with the atmosphere (House et al., 2005). Respiration of living organisms returns carbon to the atmosphere. In the ocean, a part of dead organic matter (so-called export production) escapes the ocean surface layer and sinks toward the ocean floor. Because of long turnover time of deep ocean waters, the amount of carbon stored in the ocean due to this process (called the biological pump) is comparable to the organic carbon storage on land. Changes in terrestrial biomass and soil organic matter, as well as in volume and composition of marine export production, affect atmospheric CO₂ concentration directly on annual-to-millennial timescales. Altered CO₂ concentration modifies atmospheric radiative properties and, via climatic change and direct CO₂ effect, feeds back on ecosystem production.

Figure 1 Map of land-surface albedo captured by the MODIS Satellite Instrument (Lucht et al., 2000; Schaaf et al., 2002). Regions where there were no data available, for example, due to clouds, are indicated in black. (a) January 2001: In the northern areas during the winter season, snow albedo is very high (up to 0.8, red). The boreal forest belt can be clearly seen in blue and green as trees mask snow, reduce albedo, and warm the surface air during the snow season. (b) June 2001: In comparison with January 2001, the northern land areas have a much lower albedo due to the absence of snow. In this map, the area with the highest albedo (up to 0.5, green and yellow) is the Sahara desert. High albedo in this region suppresses rainfall during the summer rainy season. Reproduced from House JI and Brovkin V (2005) Climate and air quality. In: Hassan R, Scholes R, and Ash N (eds.) *Ecosystems and Human Well-Being: Current State and Trends*, vol. 1, pp. 355–390. Washington, DC: Island Press, with permission.

Land-Surface Biophysics

In the planetary boundary layer up to 2.5 km above Earth's surface, vertical profiles of temperature and humidity strongly depend on the partitioning of energy between sensible heat and latent heat. This partitioning is, to a large extent, controlled by terrestrial ecosystems through biophysical mechanisms (Pitman et al., 2004). Over dry, bare ground, the energy is transported via sensible heat, resulting in relatively high surface-air temperatures. Vegetation canopies transpire water extracted from the root zone, increase latent heat flux upwards, and cool the surface air during the day. Transpiration is tightly coupled to photosynthesis. Both transpiration and photosynthesis are regulated by the opening of stomatal pores on the leaf's surface. Low atmospheric CO_2 levels during glacial periods led to increased stomatal conductance, lower water use efficiency (productivity per unit volume of water transpired), and reduced levels of photosynthesis.

Increased air humidity due to daily transpiration reduces heat loss in the near-surface atmosphere (greenhouse effect), helping to smooth diurnal fluctuations in temperature. Vegetation canopies also intercept part of the rainfall and effectively reduce runoff, especially during heavy rain events. Moisture that is transported to continental interiors has been transpired and precipitated several times on its way from the ocean; therefore, reduction in vegetation cover during glacial periods enhances intracontinental aridity.

Vegetation affects surface albedo, and in most cases, it reduces albedo compared to bare ground and snow. Forests are more effective than grasslands in trapping solar radiation.

This effect is particularly strong in snow-covered regions where trees extend above the snow pack, while herbaceous vegetation is covered (see Figure 1). The snow-masking effect of tree cover was likely more important in glacial climates when snow cover lasted longer in spring.

Long-Term Carbon Cycle Processes

Carbonate sedimentation

Marine-calcifying organisms such as corals and coccolithophorids have skeletons or shells of calcium carbonate (CaCO_3). After an organism's death, CaCO_3 does not dissolve but forms reefs or drops to the sea floor forming sediments. In the deep seas, carbonates are well preserved above the lysocline (about 3–4 km depth), but they dissolve below this depth. On timescales of 5000–10 000 years, carbonate sedimentation in the ocean is constrained by weathering. Since carbonate deposition in continental shelf regions (e.g., coral reef production) changes with sea level during glacial–interglacial cycles, this affects deep-sea sedimentation and leads to changes in the lysocline depth. A temporal imbalance between weathering and sedimentation causes changes in the total inventory of ocean alkalinity. Acidic water dissolves less CO_2 than basic water, and in this way, changes in CaCO_3 sedimentation affect atmospheric CO_2 concentration. This process is complicated by the fact that export flux contains not only carbonate but also organic matter that becomes mineralized on the seafloor. The latter process releases CO_2 , making sediment pore water more acidic and leading to

carbonate dissolution. Changes in organic-to-carbonate ratio (rain ratio) in export flux affect CaCO_3 sedimentation considerably, and, through lysocline dynamics, the atmospheric CO_2 level.

Anaerobic decomposition

Some dead organic matter is trapped in wetlands or marine sediments in anaerobic conditions. Decomposition of this organic matter by methane (CH_4)-producing bacteria may lead to a release of CH_4 . Most of this CH_4 oxidizes in the water column, but a part escapes to the atmosphere. Atmospheric CH_4 concentration is small but important for climate since CH_4 is 20–30 times more potent a greenhouse gas than CO_2 . CH_4 sink in the atmosphere is regulated by atmospheric chemistry that in turn is affected by plant emissions of volatile organic compounds (VOCs) such as isoprene.

Numerical Modeling as a Methodology of Feedback Analysis

The climatic effect of planting a single tree is negligibly small. Even for large-scale land-cover changes, their climatic consequences are very difficult to detect in observations because several climatic forcings operate simultaneously in the presence of substantial climate variability. In addition, regional climate can be influenced not only by local changes but also by changes in remote regions. Carrying out numerical experiments with climate and ecosystem models is one of the principle methods of testing feedback between climate and biosphere. In the usual design of sensitivity experiments, the simulations are performed twice, once when feedback is neglected and a second time when feedback is included. A difference between these two simulations indicates the importance of feedback for climate. Biophysical feedbacks studied with global climate models are hereafter referred to as biogeophysical feedbacks to stress their significance for global-scale processes.

Hot Spots of Climate–Biosphere Interaction in Quaternary

The Holocene

'Green' Sahara

Multiple proxy data reveal that during the so-called Holocene optimum, ca. 9000–6000 years BP, the vegetation cover of the Sahel was greatly extended to the north. During that period, the Sahara's climate was much wetter; many lakes and rivers, including the greatly extended Lake Chad, were present in the region. A conventional explanation of the 'green' Sahara phenomenon in the mid-Holocene, supported by many modeling experiments, is based on the long-term changes in Earth's orbital parameters. In the early-to-mid Holocene, the northern hemisphere received considerably more solar radiation during the summer. In the northern subtropical regions, this led to stronger warming over the continent than over the ocean, an increased temperature gradient between land and ocean, and, consequently, intensified monsoon-type circulation in summer which led to increased rainfall over the Sahel/Sahara region.

The North African desert differs from many other subtropical deserts. The radiative balance in the region is negative, that is, there is a net radiative heat loss over the desert. This loss is particularly due to the high albedo of the desert, as up to 50%

Figure 2 Idealized sketch of atmosphere–vegetation interactions in the Sahel/Sahara region. The signs attached to the arrows indicate the effect of the outgoing box on the incoming box; for example, increased vegetation cover leads to more radiation absorbed at the land surface. Both radiative and hydrological feedbacks are positive, that is, they amplify external changes and therefore may cause instabilities. Reproduced from Claussen M, Cox PM, Zeng X, et al. (2004) The global climate. In: Kabat P, Claussen M, Dirmeyer PA, et al. (eds.) *Vegetation, Water, Humans and the Climate: A New Perspective on an Interactive System*. Global Change: The IGBP Series, pp. 33–57. Berlin, Germany: Springer, with permission.

of incoming radiation is reflected back into space (Figure 1). The radiative mechanism for the Sahara was first explored by Jule Charney in the 1970s. He pointed out that the heat loss due to high albedo leads to a temperature gradient and induces an atmospheric circulation which maintains the sinking motion of dry atmospheric masses and suppresses rainfall over the region. Low precipitation results in little vegetation cover, and the surface albedo is determined by bare ground with a high albedo. This positive feedback supports a desert that is self-sustaining. Alternatively, if there is more precipitation, there is more vegetation. Vegetation canopy is darker than sand, so the albedo is lower, the surface temperature is higher, and the gradient in temperature between land and ocean increases, amplifying monsoon circulation and upward motion over the desert. As a result, the summer rainfall in the region increases. This radiative feedback loop gets additional support through hydrological feedback, as vegetation recycles water to the atmosphere, reduces runoff, and enhances rainfall in comparison with bare ground (Figure 2).

Both radiative and hydrological feedbacks are positive, that is, they amplify changes induced by external forcings or internal variability. Could these positive feedbacks have affected the stability of the regional climate in the past? In the early 1990s, Martin Claussen applied coupled atmosphere–vegetation model ECHAM2–BIOME to investigate the effect of different initial land-surface conditions on regional climate. In these simulations, vegetation cover responded to climate simulated by the model and vice versa. In the first simulation with present-day boundary conditions (Figure 3(a)), which started from the present-day potential vegetation, the desert in North Africa remained stable. However, when the Sahara was initially covered by forest in simulation B (Figure 3(b)), the system converged to another solution, called the 'green' Sahara. The Western Sahara is covered by a mixture of shrubs and grass; in addition, vegetation cover in the Sahel region is enhanced. Both desert and green solutions are stable for present-day conditions. At the same time, the coupled model revealed the only steady solution, 'green' Sahara, for the mid-Holocene orbital forcing (Figure 3(c)). In the dynamical system theory,

Figure 3 Summary of results obtained with an interactive atmosphere–vegetation ECHAM/BIOME model. For present-day climate, two states are stable in the model: desert Sahara as observed now (a) and ‘green Sahara’ state with enhanced vegetation cover in the Western Sahara (b) in accordance with Claussen (1994). (c) For 6000 years ago, ‘green Sahara’ is the only stable state in the model (Claussen and Gayler, 1997). Lower albedo corresponds to a higher fraction of vegetation cover. EQ, equator. Reproduced from Brovkin V, Claussen M, Petoukhov V, and Ganopolski A (1998) On the stability of the atmosphere–vegetation system in the Sahara/Sahel region. *Journal of Geophysical Research-Atmospheres* 103: 31613–31624, with permission from American Geophysical Union.

the fact that the system has one steady state for one parameter value (mid-Holocene insolation) and two states for another value (present-day orbital parameters) means that in between these points the system has undergone a bifurcation that could be associated with abrupt climate changes. Indeed, proxy data suggest abrupt changes of vegetation cover in the Western Sahara between 5000 and 6000 years BP (deMenocal et al., 2000). Later simulations with another coupled model that included interactive ocean, ECBILT-CLIO-VECODE, supported the fact that the system underwent bifurcation around 4000–6000 years BP as the green state lost its stability (Renssen et al., 2003). Some other coupled models do not show multiple states, but they all reveal a high sensitivity of rainfall in the Sahel/Sahara region to vegetation cover. In summary, strong positive vegetation–atmosphere feedback in North Africa is an important amplifier of externally induced changes in the region during the Quaternary. In particular, this feedback had contributed to abrupt desertification of the region about 5000–6000 years ago.

Northern treeline dynamics

During the mid-Holocene, the northern tundra–forest boundary was located north of its present position in many regions.

In particular, in central Siberia, the treeline (the forest limit) was shifted to the north by up to 200 km (Bigelow et al., 2003), presumably because of warmer summers, as treeline position corresponds reasonably well with July temperature isotherms of about 10–12 °C. In the northern high latitudes, changes in forest cover affect regional climate in several ways. Forests, even deciduous ones, significantly reduce the albedo of snow-covered surfaces. This is the basis for the radiative feedback between forest and surface-air temperature. Increased forest cover within large regions leads to decreased surface albedo during the snow season. This results in elevated air temperature and earlier snow melt, and a longer and warmer growing season, which favors further increase in forest area. This feedback (sometimes called taiga–tundra feedback) amplifies the climate system response to the original external forcing (Figure 4). The rate at which forest-cover changes depends on many local factors such as disturbances (fire), permafrost, soil parent material, and pH. The radiative feedback is dampened during the growing season, when trees have a denser, more productive canopy. Trees also have deeper roots than herbaceous plants and moss and transpire more water. This cools the surface air in forests as compared to tundra during summer. The hydrological feedback, although negative, is secondary

Figure 4 Simplified scheme of climate–vegetation interactions in the northern high latitudes. The signs attached to the arrows indicate the effect of the outgoing box on the incoming box; for example, increased forest (tree) cover leads to more radiation absorbed at the land surface during snow-covered periods. Changes in surface-air temperature due to forest-cover changes are amplified through sea ice–albedo feedback in the Arctic.

to the radiative feedback on the annual average. Besides, enhanced transpiration from deeper soil horizons improves soil drainage and aeration of soil mineral layers, which increases viability of tree establishment. In the Arctic environment, the radiative feedback of forests is closely linked to sea ice–albedo feedback. Elevated surface-air temperature due to increased forest cover leads to higher sea-surface temperature (SST) and decreased sea-ice area, decreased sea-surface albedo, and, finally, elevated surface-air temperature (Figure 4). Model simulation suggests that taiga–tundra feedback and its amplification by sea ice–albedo feedback led to additional warming of northern high latitudes in response to the changes in orbital forcing during the mid-Holocene (Figure 5).

Historical land-cover changes

At present, about one-third of the Earth's land cover has been modified by agricultural and forestry activities. Human-induced land-cover changes probably began in the early Holocene with development of slash-and-burn agriculture. The magnitude of these changes and their temporal dynamics on large regional scales in the preindustrial period are mostly unknown. Most models have been used to evaluate the climatic effect of reconstructed potential vegetation versus present-day land cover, and some models have been applied for testing the climatic effect of the last millennium land-cover changes using simplified assumptions about such changes prior to AD 1700. Most model simulations agree that historical deforestation led to some increase in atmospheric CO_2 and consequent warming. At the same time, an increase in albedo due to deforestation of regions covered with snow in winter, such as northern Europe, led to a radiative cooling (Figure 6). On a global scale, biogeophysical cooling was likely compensated by biogeochemical warming, but consequences for regional climate could be substantial. Biogeophysical effects due to the increasing deforestation rate could have contributed to an observed stabilization of

Figure 5 Role of vegetation feedback in the mid-Holocene climate in terms of annually averaged surface-air temperature ($^{\circ}\text{C}$) in CLIMBER-2 model simulations of the mid-Holocene climate (6000 years BP). (a) Difference between the mid-Holocene and the present-day simulations. (b) Contribution of the biogeophysical feedback (difference between mid-Holocene simulations with interactive vegetation and vegetation prescribed from present-day simulation). EQ, equator. the temperature during the second half of the nineteenth century and damped the CO_2 warming in the twentieth century.

Last Glacial Maximum

The Last Glacial Maximum (LGM) was characterized by cold and dry conditions that led to a great reduction in forest cover in the Northern Hemisphere. Boreal evergreen forests and temperate deciduous forests were fragmented, while European and East Asian steppes were greatly extended (Prentice et al., 2000). Tropical forests in the Americas and Africa were reduced as well. These changes toward herbaceous and sparser vegetation cover had considerable implications for climate.

Biogeophysical feedbacks

Model simulations using glacial boundary conditions suggest that reduction in forest cover amplified LGM coldness and aridity. Southward displacement and fragmentation of forest biomes in North America and Eurasia led to increased albedo during the snow period and a regional decrease in temperature by several degrees (Figure 6). Global cooling effect of reduced vegetation cover during the LGM is estimated in 0.6°C (Crucifix and Hewitt, 2005; Jahn et al., 2005). Reduction in forest cover led to less transpiration and increased aridity of the continental interiors. Presumably, physiological effects of lowered CO_2 levels during the LGM resulted in increased canopy conductance of C_3 plants and a consequent drop in

Figure 6 Effects of historical land-cover changes on global mean annual temperature ($^{\circ}\text{C}$) simulated by CLIMBER-2 model. H_P , biogeophysical effect only (mainly due to albedo changes); H_C , biogeochemical effect only in response to atmospheric CO_2 increase; H , both biogeophysical and biogeochemical effects. Shown here are the differences between simulations with and without land-cover changes. Reproduced from Brovkin V, Sitch S, von Bloh W, et al. (2004) Role of land cover changes for atmospheric CO_2 increase and climate change during the last 150 years. *Global Change Biology* 10: 1–14, with permission of Blackwell Publishing.

water-use efficiency (water used per unit of photosynthetic production; **Figure 7**; Harrison and Prentice, 2003).

Terrestrial CO_2 feedback

Cold and dry climates as well as low CO_2 levels led to decreased plant productivity and biomass storage during the LGM. Land areas in the Arctic were more extensive due to lowered sea levels, but regional ecosystems were not very productive. To some degree, reduction in boreal forests was compensated by the establishment of new forests along the exposed shelf regions in tropical regions such as southeast Asia, but on a global scale, terrestrial carbon storage was drastically reduced. Vegetation models applied to LGM climate-change scenarios reveal a range of decrease in terrestrial storages, from several hundreds to thousands of petagrams of carbon (PgC ; 10^{15} g C). A central estimate of about 600–700 PgC is higher than changes suggested by a decline in deep ocean $\delta^{13}\text{C}$ (about 500 PgC). The later proxy should be carefully interpreted since oceanic $\delta^{13}\text{C}$ is also affected by changes in oceanic circulation and marine productivity. Decrease in northern peat storage due to expansion of ice sheets and increased aridity also contributed to the release of land carbon to the atmosphere, but the magnitude and timing of peat changes are uncertain. A reduction in the terrestrial carbon pool during glacial periods provides a negative (stabilizing) feedback to climate by increasing atmospheric CO_2 concentration. This feedback is rather weak since most of the released terrestrial carbon ends up in the ocean. After carbonate compensation on timescales of 5000–10000 years, 500 PgC of land carbon source corresponds to about a 20 parts per million by volume (ppmv) increase in atmospheric CO_2 concentration (Archer et al., 2000).

Dust feedback

In semiarid regions, reduced vegetation cover means more bare ground exposed to wind erosion. During glacial periods, these sparsely vegetated regions were a source of mineral aerosols for the atmosphere. Higher eolian dust transport during glacial periods is supported by sediment data (Kohfeld et al., 2005). Mineral aerosols diffuse light and reduce the amount of solar

Figure 7 Role of biogeophysical feedback in the Last Glacial Maximum (LGM) climate as simulated by CLIMBER-2 model. Shown are annually averaged surface-air temperature differences ($^{\circ}\text{C}$). (a) A difference between the LGM and the present-day simulations. (b) Change in temperature due to the biogeophysical feedback. radiation that reaches the surface. Radiative transfer models estimate that increased atmospheric dust concentrations during the LGM led to about $2\text{--}3 \text{ W m}^{-2}$ reduction in radiative forcing in the tropics, which roughly corresponds to the radiative effect of lower glacial CO_2 levels in the region (Claquin et al., 2003). As a result, sparser vegetation cover amplified LGM cooling through the dust feedback.

Marine biota feedback

Several hypotheses aimed at explaining glacial–interglacial changes in atmospheric CO_2 invoke changes in marine

ecosystem structure and export production. Sub-Antarctic proxy data suggest that export production in the sub-Antarctic Atlantic was enhanced during the LGM, presumably because of iron fertilization in response to increased eolian dust deposition. Some other regions, such as the Pacific, show few changes, while productivity in Antarctic Ocean was reduced. Iron fertilization could be responsible for some drawdown of atmospheric CO_2 levels at the LGM, but it cannot explain the whole range of 80–100 ppmv change (Kohfeld et al., 2005). Increased organic to CaCO_3 ratio in export production (e.g., due to silica leakage) could have substantially lowered the atmospheric CO_2 through the sediment response. However, recent data show that the ratio of organic to CaCO_3 flux that reached the seafloor is almost constant. Coral reef production was reduced during the LGM in response to lowered sea levels and surface cooling (Kleypas, 1997). Reduced shallow-water sedimentation could have led to an increase in oceanic total alkalinity, but this effect might also have been offset by decreased continental weathering during the LGM. In summary, the marine biosphere was likely to have provided positive feedback to the atmosphere by amplifying LGM cooling through lowering of atmospheric CO_2 , but the magnitude of this feedback and the precise mechanisms are still not well known.

Weathering feedback

On a timescale longer than several thousand years, atmospheric CO_2 is strongly affected by changes in carbonate and silicate weathering. Increased weathering lowers atmospheric CO_2 concentration through oceanic carbonate compensation. Vascular plants contribute to the weathering as roots' respiration and litter mineralization lead to elevated soil CO_2 concentrations and the formation of carbonic acid, which enhances weathering of parent soil material. Model estimates of changes in weathering rates during the LGM are equivocal as several factors influencing global weathering flux, such as increased ice-sheet areas, shelf exposure, and decreased runoff, almost nullify each other (Munhoven, 2002).

Methane and atmospheric chemistry feedback

During the LGM, atmospheric CH_4 concentration (about 400 ppbv) was much lower than in the Holocene (600–750 ppbv). Decreased concentration of CH_4 led to small but not negligible additional cooling. The plausible explanation of the lowered CH_4 concentration is that terrestrial CH_4 sources (e.g., wetlands and biomass burning) were lower during the LGM. In particular, the extent of wetlands was reduced in the cooler and drier LGM climate, especially in the northern high latitudes, while this reduction might have been offset by the establishment of wetlands on exposed tropical shelves. Another important factor could be a change in atmospheric chemistry. Model simulations suggest that emissions of VOC were lower during the LGM due to reduction in forest cover, resulting in increased atmospheric concentration of the OH radical (an atmospheric 'detergent'), and this may have led to an increased sink for CH_4 in the atmosphere (Valdes et al., 2005). In summary, biospheric feedback amplified LGM cooling through lowering of CH_4 concentration,

Figure 8 Role of biogeophysical feedback in the climate of last interglacial and glacial inception as simulated by CLIMBER-2 model. while CH_4 -regulating mechanisms involving VOC emissions are not yet fully explored.

The Last Interglacial and Glacial Inception

During the last interglacial, the increase in summer insolation in the northern hemisphere was stronger than during the Holocene. Pollen evidence and model simulations suggest that summer climate in northern regions was substantially warmer than at present and that forest cover was more extensive in the temperate and high northern latitudes. The vegetation feedback amplified the warming in model simulations (Figure 8(a)). This temperature increase anomaly is mainly due to the northward advance of boreal forest during the warmer climate of the last interglacial. Conversely, the later cooling trend triggered by the decreasing boreal summer insolation was facilitated by the vegetation response (Figure 8(b)). Most climate model simulations suggest that a southward shift

of northern treeline is crucial for the initiation of glacial inception: if vegetation cover is prescribed to the values simulated for the last interglacial, then cooling in the north due to declining insolation is not sufficient to initiate ice sheet growth. Treeline retreat amplifies cooling through increased albedo, fostering permanent snow cover on land during the glacial inception.

Conclusions

Analysis of climate–biosphere feedbacks and their role in climate system dynamics during the Quaternary is a new, rapidly developing scientific field. Hypotheses about roles of biological mechanisms in past climate dynamics usually emerge from the analysis of geological data, but quantification of feedback is impossible without modeling. Today, the main methodology of feedback analysis is numerical modeling using climate system models of different complexities, from high-resolution general circulation models (GCMs) to simplified conceptual models. Model results are tested against proxy data for biogeochemistry and vegetation cover.

A picture emerging from model simulations and proxy data analysis is that biospheric feedback played a substantial role in the evolution of Quaternary climate, but many details are uncertain. In some cases, such as glacial inception, model simulations agree that the dynamics of northern treeline is an important mechanism amplifying cooling due to summer insolation decrease in the northern high latitudes. Analysis of climate–vegetation interactions in North Africa suggests that biospheric feedback might be strong enough to cause abrupt, irreversible changes in the region. At the same time, the role of biological mechanisms in glacial–interglacial CO₂ changes remains far from clear.

The understanding of the role of biospheric feedback in the past has important implications for future climate projections. The challenge in Earth system science is to constrain feedback mechanisms within the models based on available – and newly developing – proxies for biological activities in the past.

Effects of Atmospheric Dust

Micrometer-sized dust particles that are lifted from soil surfaces in arid and semiarid regions by strong surface winds contribute a large fraction to the global atmospheric aerosol mass load and aerosol optical thickness (Intergovernmental Panel on Climate Change (IPCC), 2001). They influence the Earth's radiation balance, biogeochemical processes, and atmospheric chemistry in several ways, which are only partly understood and remain largely unquantified (Figure 1). Atmospheric dust reflects and to some extent absorbs incoming solar radiation, and it also absorbs and emits outgoing thermal radiation due to its relatively large particle sizes. Thus, it directly influences top-of-the-atmosphere and surface radiation fluxes as well as atmospheric heating rates and stability. Such changes in heating rates also may influence cloud formation. In addition, dust provides cloud condensation nuclei (CCN) that are particularly effective for ice nucleation and thus potentially influence cloud optical properties, precipitation formation, and cloud lifetimes (indirect aerosol effects). Another potentially important effect of dust is its influence on oceanic export production of marine microorganisms by supplying nutrients into the ocean surface, overcoming limitations of essential nutrients such as iron, or enhancing nitrogen assimilation. Dust fertilizes some terrestrial ecosystems by depositing nutrients into soils, and it influences atmospheric chemistry due to heterogeneous reactions on the particle surfaces. Emission, atmospheric concentration, and deposition of dust are strongly dependent on atmospheric parameters and surface properties, and they are therefore very variable on a wide range of timescales; for example, dust production and dispersal was considerably enhanced in glacial times compared to modern conditions. The strongest emphasis in investigations of the effects of dust aerosol has been on quantification of the direct radiative effect of dust under present-day conditions, whereas only a few studies have examined dust distributions under different climates such as the Last Glacial Maximum (LGM) or with future climate scenarios. Because quantitative data of the atmospheric dust content cannot be obtained from observations alone, such studies must rely on results of large-scale models of dust emission, transport, and deposition.

Atmospheric Dust

Soil dust aerosol particles are produced in arid and semiarid continental regions (Figure 2), including the Sahara and the Sahelian region, the Arabian Peninsula, the Gobi and Taklamakan deserts in Asia, and the Australian and South American deserts (Prospero et al., 2002). Most of the dust contained within the global atmosphere is emitted from the North African (50–70%) and Asian deserts (10–25%). Wind tunnel experiments and theoretical considerations show a dependence of dust emissions to the third or fourth power of the surface

wind friction velocity. Dust production is initiated when the surface wind friction velocity in the source region exceeds a threshold value that depends on surface properties such as the size and distribution of roughness elements, the soil texture, and soil moisture (Marticorena and Bergametti, 1995).

Fine soil particles with diameters smaller than 10 μm , which can be transported by winds over large distances, are released from the soil matrix when larger wind-blown sand grains strike on the surface, releasing the smaller particles through the process of saltation. Dust emissions are particularly strong in areas that contain fine and loose sediments. A good agreement between maximal occurrence of dust over land surfaces observed by satellites and the location of enclosed topographic depressions has been observed (Prospero et al., 2002). In such areas, fine sediment may have accumulated during the past. Either lake sediments have formed in such depressions, in case they were filled with water during wetter climate periods, or these areas may have been end points for riverine transport of fine particles. Dust emission strength in a potential source region depends on the aerodynamic surface roughness length because structural elements such as rocks or vegetation increase the transport of wind energy to the surface but also partly absorb this energy, increasing the threshold wind friction velocity required for dust emission (Marticorena and Bergametti, 1995).

The presence of crusts can reduce dust emission from a soil surface. Also, the loss of fine soil material by wind deflation can lead to a decrease of dust production from a specific area over time. On the other hand, surface disturbances as a consequence of cultivation of soils in dry regions may lead to enhanced dust emissions (e.g., as observed during the 'dust bowl' events in the United States in the 1930s and 1950s). The contribution of this enhanced dust emission to the global dust load may be considerable in semiarid regions, but the magnitude is uncertain on the global scale. Although IPCC (2001) estimated a contribution of this enhanced dust of up to 50% to the global dust load, Tegen et al. (2004) concluded that this contribution is much smaller, probably <10% globally.

Dust injected into high atmospheric levels of up to several kilometers can be transported over horizontal distances of thousands of kilometers by strong wind systems. Remote sensing instruments can clearly distinguish such dust plumes over dark ocean surfaces. Most prominently, dust emitted in the globally strongest dust source, the Sahara desert, can be carried across the North Atlantic to North and Central America (Prospero and Lamb, 2003) and is even found as far downwind as the Amazon basin. Also, large amounts of Asian dust are carried over the North Pacific toward the mid-Pacific islands and North America.

Dust particles are removed from the atmosphere either by wet deposition (i.e., scavenging through precipitation in the water or ice phase) or by dry deposition, which is the gravitational settling in addition to turbulent mixing toward the surface. Close to desert dust source regions, the gravitational

sedimentation is responsible for the major part of dust deposition, whereas wet deposition dominates the removal of far-traveled dust over remote ocean areas (Jickells et al., 2005). The efficiency of the dust scavenging from the atmosphere may increase with distance from the source regions, when soluble components coating the dust surfaces make the particles increasingly hygroscopic. Whether dust is removed from the atmosphere by dry or wet processes affects the solubility of any trace elements transported with the dust. The atmospheric lifetime of dust depends on the deposition velocities of the different particle sizes. Atmospheric lifetimes of dust depend on the particle size and range from a few hours for particles larger than $10\ \mu\text{m}$, which are quickly removed by gravitational settling, to 10–15 days for submicron particles that are mostly removed by wet deposition (Seinfeld and Pandis, 1997).

Figure 1 Overview of linkages between atmospheric dust and climate indicating direct and indirect aerosol effects as well as the potentially important role of oceanic dust deposition for marine microorganisms.

Dust Measurements

Although *in situ* observations of airborne and deposited dust particles help us to understand atmospheric dust properties, they cannot describe dust distributions globally because dust is highly variable in space and time and the observations can only cover limited regions. *In situ* observations of dust include multiyear concentration measurements from approximately 30 stations of the Miami oceanic network (Prospero and Lamb, 2003), optical thickness measurements by sun photometers (e.g., the AERONET network), and aerosol lidar observations (Ansmann et al., 2005). In contrast, remote sensing using satellite instruments covers large areas of the globe, but it is nearly impossible to accurately quantify dust properties above land surfaces from such retrievals. Over dark ocean surfaces, retrievals of dust optical thickness and angstrom parameters are possible with some confidence (Kaufman et al., 2001), but such measurements only document dust that is far removed from source areas. Multiyear retrievals of the daily distribution of absorbing aerosols with the Total Ozone Mapping Spectrometer instrument (Herman et al., 1997) have provided useful qualitative information of dust plume occurrences over both ocean and land surfaces (Figure 3).

Measurements of deposited dust provide the only method to obtain information on the atmospheric dust content during past climate periods. Such deposition records include terrestrial loess deposits, marine sediments, and dust concentration in ice cores (Kohfeld and Harrison, 2001). Notable examples of loess deposits that were formed during glacial periods are located in North America, the Eurasian Continent, and the South American Pampa region. Deposition fluxes in loess deposits have been as high as $20000\ \text{g m}^{-2}\ \text{year}^{-1}$ during glacial periods. Dust particles deposited in the loess regions consists of coarser particles ($10\text{--}63\ \mu\text{m}$) that have not traveled far from the source

Figure 2 Eleven-year annual average of the Total Ozone Mapping Spectrometer (TOMS) Absorbing Aerosol Index.

Figure 3 Distribution of global dust source areas, indicating unvegetated desert areas, densely vegetated areas that cannot act as dust sources (dark green), and areas where remote sensing data indicate bare soils for part of the year (light green) and can thus potentially act as seasonal source areas for soil dust emission. Also shown are modeled preferential ‘hot spot’ dust emission areas (brown). This distribution of source areas was used, for example, in the dust emission model described in [Werner et al. \(2003\)](#).

regions. In contrast, marine sediment records are good indicators for intermediate and long-distance transport. Mean grain sizes in marine sediments are typically $<10\ \mu\text{m}$, although larger grains are found in sediments close to continental source areas. Accumulation rates in marine sediments are on the order of $1\text{--}10\ \text{g m}^{-2}\ \text{year}^{-1}$, with maxima as high as $100\ \text{g m}^{-2}\ \text{year}^{-1}$. Marine sediments suggest an approximately twofold increase in dust deposition fluxes in the glacial compared to interglacial periods in the tropics and mid-latitudes ([Kohfeld and Harrison, 2001](#)). Ice core concentration data are records of long-distance transport of dust with particle sizes smaller than $5\ \mu\text{m}$. Records of increases in the LGM indicate that dust concentrations are highest in the Antarctic ice cores that cover several glacial cycles, with an approximately tenfold increase in the Vostok and a 40-fold increase in the European Project for Ice Coring in Antarctica (EPICA) core compared to modern concentrations ([Delmonte et al., 2002](#)). Although the changes in dust fluxes at these locations are very high, the actual fluxes are only on the order of $0.0001\text{--}0.01\ \text{g m}^{-2}\ \text{year}^{-1}$. The isotopic and mineralogical properties of ice core dust allow the determination of source areas and transport. Current studies indicate that glacial dust arriving at Antarctica originates mostly in southern South America, with minor sources in northern New Zealand, or the Antarctic dry valleys; dust arriving in Greenland originates in the Asian deserts ([Basile et al., 1997](#); [Biscaye et al., 1997](#)). Ice core data also show the timing of increase and decrease of dust fluxes compared to changes in other environmental parameters, such as temperature, CO_2 , and CH_4 ([Petit et al., 1990](#)). Dust concentrations increased after the onset of glacial cooling and lowering of atmospheric CO_2 . This timing may lead to explanations of the cause of increased dustiness as well as feedback of dust on climate parameters such as temperature, precipitation, and the radiation balance.

Dust Variability

Soil dust aerosol not only shows distinct spatial patterns but also is temporally very variable at different timescales. Soil dust aerosol distributions respond to changes in global climate conditions, such as the overall intensity of winds that entrain dust into the air, and changes of the hydrological cycle that can affect the extent of source areas as well as the length of time that dust remains in the atmosphere. Within individual source areas, dust emissions mostly follow a seasonal cycle with distinct spring and summer maxima, when strong surface winds occur and the soils are unvegetated ([Figure 4](#)). Dust production can also vary from year to year as a consequence of changes in climate conditions. For example, in the Sahara, dust emissions are found to vary interannually in connection with the Sahelian rainfall deficit ([Prospero and Lamb, 2003](#)). On decadal timescales, an increase in Saharan dust emissions has been observed since the late 1960s through the 1980s, and the emissions have remained at a high level since then. Long-term records of dust deposition measured in ice cores, marine sediments, and loess deposits show a clear change in deposition fluxes between interglacial and glacial climate periods, when dust was approximately 2–10 times increased globally compared to interglacial periods. This increased dustiness is likely due to a combination of different factors, such as increased aridity, reduced vegetation, increased availability of fine sediment, and stronger surface winds in glacial climates. Higher wind speeds could produce stronger dust emission fluxes from soil surfaces compared to modern conditions; increased aridity expands those areas with drier soils and reduced vegetation where soil deflation by wind is possible. Atmospheric dust loads could also have been enhanced in

Figure 4 Seasonal distribution of modeled dust aerosol optical thickness based on the results of Tegen et al. (2004).

climate conditions as a consequence of the weakened hydrological cycle with reduced washout of atmospheric dust particles. The best documented period of increased dustiness in the Quaternary is the last glacial period (approximately 17 000–23 000 years ago; Kohfeld and Harrison, 2001).

Models of the Dust Cycle

Increasingly complex regional and global-scale models of the dust cycle have been developed in order to quantify the atmospheric dust distribution with the aim of supporting investigations of dust effects. The atmospheric dust content computed by these models depends on dust emissions, which are determined by surface wind speeds, and surface properties such as roughness length, vegetation cover, soil moisture, and soil texture. Recently developed models explicitly prescribe seasonal vegetation cover (Werner et al., 2003), masking dust sources, as well as the occurrence of topographic depressions in dry, unvegetated areas as indicators of preferential sources containing fine and loose sediment particles that can be easily deflated under strong wind conditions (see Figure 2).

Large-scale data sets of soil properties are difficult to obtain on global scales because the most active dust sources lie in remote areas that cannot easily be accessed. Another major problem in computing dust emissions from wind deflation is insufficient model resolution because peak gusts that are responsible for the strongest dust events remain largely unresolved in large-scale global models. Parameterizations of subgrid scale variability surface winds (Cakmur et al., 2004) provide only moderate improvements in computations of dust emissions.

Table 1 Range of model-based estimates of emission fluxes, atmospheric burden, and atmospheric lifetimes of soil dust aerosols^a

	Dust emission (Mt year ⁻¹)	Atmospheric burden (Mt)	Atmospheric lifetime (days)
Modern	1100–3000	8–36	2.8–7.1
LGM	2400–9000	23–94	3.5–5.5
Ratio LGM/modern	1.4–3.0	1.4–2.8	0.9–1.3

^aGiven are the ranges of minimum and maximum values from model calculations by various authors; summarized in Zender et al. (2004) and Harrison et al. (2001), including also the results from Werner et al. (2003).

Apart from models of present-day dust distributions, the LGM has been a major focus for dust modeling (Table 1). During glacial periods, eolian deposition rates were approximately 2–20 times higher than today (Kohfeld and Harrison, 2001) (Figure 5), and changes in boundary conditions such as ice sheet extent and atmospheric trace gas concentrations are reasonably well known. Models that only consider the influences of increased surface wind speeds and the reduced intensity of the hydrological cycle on dust emission and deposition fluxes at the LGM are unable to reproduce the observed strong increase in dust deposition at high latitudes. The increase in dust source areas caused by exposure of continental shelves is likewise unable to explain the increased high-latitude dust signal. Incorporating increases in dust sources from changes in vegetation cover increases the modeled atmospheric dust loads at high latitudes, consistent with the high dust fluxes observed in polar ice cores (Mahowald et al., 1999; Werner et al., 2003). The potentially large effect of dust aerosol supplied by glacial outwash and the increase in the areal extent of

Figure 5 (a) Patterns of modern global dust deposition fluxes comparing a model result (Tegen et al., 2004) with local dust fluxes derived from measurements of marine sediments, sediment traps, terrestrial loess deposits, and ice cores for the late Holocene compiled by Kohfeld and Harrison (2001). (b) To indicate the enhancement of dust deposition fluxes during glacial climate, the ratio of the observed dust fluxes between the Last Glacial Maximum and the late Holocene is shown.

dry lake beds during the LGM have not yet been factored into global dust models.

Global-scale models are not always useful for investigation of regional-scale dust processes, especially in areas close to source regions, since the horizontal resolution of typically $3\text{--}5^\circ$ in global models and the necessarily simplified emission and deposition parameterizations are too crude to resolve small-scale dust processes and enable comparisons to observations. Regional models of dust emission, transport, and deposition exist for key regions, including the Sahara desert and Asia (Sokolik et al., 2001). Such regional-scale models are well suited for simulation of individual dust storm events as well as for comparisons with *in situ* observations made during field experiments. Although the topography, soil conditions, and

small-scale extreme wind events are simulated more realistically in regional compared to global models, uncertainties in the parameterization of key processes and input data on meteorological fields and soil properties remain.

Particle Properties

Dust aerosol particle sizes determine their optical and microphysical properties, as well as atmospheric lifetimes. Close to source regions, the median dust particle diameters are observed to be approximately $60\text{--}100\text{ }\mu\text{m}$; particles in this size range can most effectively be lifted from the ground by surface winds. Because large dust particles settle back to the ground quickly,

dust that has been transported thousands of kilometers away from the source has a median size of approximately $2\ \mu\text{m}$ (Seinfeld and Pandis, 1997).

The mineral composition of dust particles reflects the mineralogy of the rocks at the Earth's surface; some main constituents are quartz, feldspars, carbonates, and clays. Dust particles from different source regions can have specific mineralogical composition and, as a consequence, different chemical composition. Claquin et al. (1999) summarized available information to compile global maps of mineral composition of soils in dry areas by relating soil mineralogy to soil types. They found that quartz, with approximately 70% of the mass, is the most abundant mineral in the silt size fraction of the soil (particles in the size range of $2\text{--}50\ \mu\text{m}$ diameter), and illite is the most abundant clay mineral (contributing up to 50% regionally to the clay fraction). The radiative and chemical properties of dust can change during transport when dust surfaces coat with soluble sulfates and nitrate species and are processed by clouds.

Dust Effects

Direct Effect

Incoming solar radiation is partly reflected and partly absorbed by dust particles in the atmosphere. With mass median diameters of $2\ \mu\text{m}$ or larger, these particles also absorb and emit outgoing terrestrial radiation. The radiative effect of dust particles depends on their optical properties (i.e., their size distribution and complex refractive index), which are either determined by laboratory and field measurements or retrieved by remote sensing (Sokolik et al., 2001). Although direct measurements have a considerable uncertainty range, remote sensing retrievals of dust properties may be influenced by the presence of other aerosol types besides dust or by thin cirrus clouds, or by underestimation of the nonsphericity of dust particles. Dust aerosol radiative properties are strongly influenced by their hematite content, which mostly controls the absorption of incoming solar radiation by the particles. From size and complex refractive indices of the particles, aerosol extinction efficiency (which determines the light attenuation per size fraction), the single scattering albedo (which is the ratio of scattering and total extinction of solar radiation), and the asymmetry parameter (which quantifies the ratio of forward scattered light) can be computed using Mie theory, which is a theory of the scattering of electromagnetic radiation by spherical particles. These parameters are then used to compute the fractions of absorbed and transmitted radiation passing through an aerosol layer. Radiative forcing by dust, defined here as the attenuation of radiation caused by the presence of atmospheric dust, rather than the radiative impact of dust enhancement from human activities, is generally negative over dark ocean surfaces. However, over bright desert surfaces, the net radiative effect of dust depends on their optical properties, and it can be positive for strongly absorbing particles (Figure 6). At the top of the atmosphere, the negative and radiative forcing by dust can partly cancel in the global mean (IPCC, 2001). Measurements of dust optical properties from remote sensing (Kaufman et al., 2001) have led to the conclusion that the net radiative forcing due to dust is negative in the global mean, indicating that enhanced dust aerosol loads would lead to regional cooling.

Figure 6 Schematic representation of reflection and absorption of incoming solar radiation in the absence and presence of a layer of dust aerosol, above a bright, highly reflective surface, and a dark absorbing surface. The dust layer partly reflects and absorbs incoming solar radiation; from space the dust appears bright over a dark surface (e.g., the ocean), the dust absorption may be sufficient to appear dark above a bright surface (bright desert or ice cover). Thus, depending on dust optical properties, it may lead to an enhancement or a reduction of energy input into the globe.

The radiative effect of higher dust loads during the LGM has been investigated by Claquin et al. (2003). The authors computed the difference in the top-of-the-atmosphere radiation between the LGM and present-day dust loads from a model simulating past dust distribution, which were obtained from results of a simulation taking into account changes in climate parameters and vegetation density for glacial conditions. The estimated change in top-of-the-atmosphere radiative forcing by the enhanced dust load (Figure 7) ranged from -0.3 to $-0.9\ \text{W m}^{-2}$ at northern high latitudes. This effect is small compared to the radiative effects due to the expansion of ice coverage at the LGM, which results in a radiative forcing of approximately $-19\ \text{W m}^{-2}$ at latitudes between 45° and 90° N. At low latitudes between 15° S and 15° N, Claquin et al. (2003) estimate a decrease in incoming solar radiation fluxes of -1 to $-1.4\ \text{W m}^{-2}$ caused by the approximately doubled dust load at the LGM, which is of comparable magnitude to the decrease in greenhouse forcing by $-1.8\ \text{W m}^{-2}$ due to the reduced CO_2 concentration at the LGM. These results indicate that the enhanced atmospheric dust may have contributed to glacial cooling at low latitudes, whereas it played only a small role in the radiation balance at high latitudes.

Semidirect and Indirect Effects

Radiative forcing by dust not only affects the radiation balance of the earth directly but also influences the energy distribution within the atmosphere. At the surface below a dust cloud, incoming solar radiation is reduced, which mainly causes a decrease in latent heating and therefore a weakening of the hydrological cycle (Miller et al., 2004). Together with atmospheric heating in the presence of a dust cloud, this may lead to a reduction in cloud cover, which is called the semidirect

Figure 7 Net changes in solar radiation at the top of the atmosphere by enhanced atmospheric dust loads during the Last Glacial Maximum (LGM). Shown is the difference in radiation fluxes between LGM and modern conditions, taking into account enhanced dust loads at the LGM. Dust optical properties were based on the assumption of an internal mixture of quartz minerals with 2% hematite. Modified from Claquin T, Roelandt C, Kohfeld KE, et al. (2003) Radiative forcing of climate by ice-age atmospheric dust. *Climate Dynamics* 20: 193–202, Figure 3b. Copyright Springer-Verlag.

aerosol effect. Hansen et al. (1997) showed with a simplified global atmospheric model that slightly absorbing aerosols, which have a negative direct radiative effect, may actually cause warming as a consequence of the semidirect effect.

Aerosol particles influence the formation and lifetimes of clouds via the so-called indirect aerosol effect, although the role of soil dust particles in these processes remains unclear. Wurzler et al. (2000) found that the coating of dust by soluble particles enhances their ability to form CCN. In addition, dust particles are effective nuclei for ice clouds; Ansmann et al. (2005) found ice formation in an altocumulus cloud in the presence of dust at 10–20 K higher temperatures than in the absence of insoluble particles, indicating the potentially important role of dust for ice nucleation. This process would not only affect the radiative properties of clouds but also enhance the formation of precipitation. However, the magnitudes of these effects are still unknown.

Effect of Dust on Ocean Biogeochemistry

Deposited soil dust particles are hypothesized to add essential nutrients to terrestrial and marine ecosystems. In particular, the increase in productivity of oceanic microorganisms by addition of iron has received much attention in recent years (Jickells et al., 2005). Microorganisms use iron in a variety of enzyme systems, including those for photosynthesis and nitrogen fixation. Soils contain an average of 3.5% iron. The iron content of dust particles is variable, but this uncertainty is small compared with other uncertainties in the iron cycle. Iron solubility in soil dust particles at source areas is on the order of 1%. Higher solubilities of aerosol iron of locally up to 40% have been reported in atmospheric particles due to photochemical processes (photoreduction of FeIII to FeII) and aerosol cloud processing. In nutrient-rich regions of the ocean, the addition of iron can enhance primary production,

species composition, and CO₂ uptake, whereas in oligotrophic regions such as the subtropics, the nutrient supply from dust aerosol can enhance nitrogen fixation. Several field studies show that plankton productivity and CO₂ drawdown are enhanced in nutrient-rich regions when iron is added, but it is unknown if dust is important for oceanic CO₂ uptake at the global scale. Different biogeochemical models have derived different results; one consequence of dust seems to be a change in planktonic species composition (Bopp et al., 2003).

Glacial–interglacial changes in ocean export production are suspected to have contributed to CO₂ drawdown, assuming that stronger dust deposition fluxes (see Figure 5) enhanced primary productivity. The effects of enhanced dust deposition during glacial periods have been investigated by Kohfeld et al. (2005), who analyzed sediment records of marine productivity at the peak and the middle of the last glacial cycle and found that iron fertilization and associated mechanisms can be responsible for up to half the observed CO₂ drawdown.

Other Effects

Apart from the direct and indirect effects of soil dust aerosol on the climate, dust also affects atmospheric chemistry by providing reactive surface areas for heterogeneous reactions (Dentener et al., 1996), influencing tropospheric ozone concentrations and the atmospheric sulfate and nitrate cycles. Sulfate reactions occur mainly with calcite in the dust aerosol, which is converted to gypsum. Bonasoni et al. (2004) observed that in the Mediterranean region the lowest surface ozone concentration occurred in the presence of coarse dust aerosol, indicating an important role of dust for ozone chemistry.

In addition to these processes, dust storms can adversely affect human quality of life. Dust storms strongly reduce visibility in the atmosphere, causing traffic problems in regions with frequent dust events. Strong exposure to dust has also been related to health problems such as silicosis.

Conclusion

Although the cycle of dust emission, atmospheric transport, and deposition has been well researched and a wide array of data exist on the properties of dust aerosols, their direct and indirect effects on the climate and atmospheric chemistry remain poorly quantified. The strong spatial and temporal variability of the atmospheric content and properties of the dust particles continue to cause challenging problems in quantifying atmospheric dust properties at global scales.

Thermohaline Circulation

S Rahmstorf, Potsdam Institute for Climate Impact Research, Potsdam, Germany

This article is reproduced from the previous edition, volume 1, pp. 739–750, © 2007, Elsevier B.V.

"It appears to be extremely difficult, if not quite impossible, to account for this degree of cold at the bottom of the sea in the torrid zone, on any other supposition than that of cold currents from the poles; and the utility of these currents in tempering the excessive heats of these climates is too evident to require any illustration."

Sir Benjamin Thompson (1797)

What is the Thermohaline Circulation?

In 1751, the captain of an English slave-trading ship made the first recorded measurement of deep ocean temperatures – he discovered that the water a mile below his ship was very cold, despite the subtropical location. In 1797, another Englishman, Benjamin Thompson, correctly explained this discovery by cold currents from the poles, as part of what later became known as the thermohaline circulation (THC).

As opposed to wind-driven currents and tides (the latter are due to the gravity of the Moon and the Sun), the THC is that part of the ocean circulation which is driven by fluxes of heat and freshwater across the sea surface and subsequent interior mixing of heat and salt; hence the name thermohaline. (Geothermal heat sources at the ocean bottom play a minor role.) The term THC thus refers to a particular driving mechanism; it is a physical, not an observational, concept.

The distinction of thermohaline versus wind-driven circulation originates in a nineteenth-century dispute on whether ocean currents are primarily due to the wind pushing along the water or whether they are 'convection currents' due to heating and cooling, or evaporation and precipitation. In 1908, Johan Sandström performed a series of classic tank experiments at Bornö oceanographic station in Sweden to investigate both possibilities (Sandström, 1908), describing the properties of 'wind-driven circulation' and 'thermal circulation.' To include salinity, the latter was later extended to 'thermohaline circulation,' a term that by the 1920s appeared in the classic oceanography textbook by Defant (1929).

The ocean's density distribution, which determines pressure gradients and thus circulation, is affected by currents and mixing. Thermohaline and wind-driven currents therefore interact in nonlinear ways and cannot be separated by oceanographic measurements. There are thus two distinct physical forcing mechanisms but not two uniquely separable circulations. Changing the wind stress will alter the THC; altering thermohaline forcing will also change the wind-driven currents.

A related, complementary concept is that of meridional overturning circulation (MOC). This refers to the north-south flow as a function of latitude and depth, often integrated in east-west direction across an ocean basin or the globe and graphically depicted as a stream function. The streamlines typically show a large-scale slow overturning motion of the ocean. The MOC can be easily diagnosed from a model, and in principle it can be measured in the ocean.

Although the terms THC and MOC are often inaccurately used as if synonymous, there strictly is no one-to-one relation between the two. The MOC includes clearly wind-driven parts, namely the Ekman cells consisting of the transport in the near-surface Ekman layer and a return flow below it. A direct contribution of wind-driven currents even to the large scale, deeper overturning is being increasingly discussed. On the other hand, the THC is of course not confined to the meridional direction; rather, it is also associated with zonal overturning cells. Hence, care should be taken with the terminology: The term THC should be reserved for a particular forcing mechanism – for example, when discussing the influence of cooling or freshwater forcing on the ocean circulation. The term MOC should be used when describing a meridional flow field, for example, from a model, which most often will show a mix of both wind-driven and thermohaline flow.

The following are key features of the THC:

- Deep water formation: The sinking of water masses, closely associated with convection, which is a vertical mixing process. Deep water formation takes place in a few localized areas (Figure 1): the Greenland-Norwegian Sea, the Labrador Sea, the Mediterranean Sea, the Weddell Sea, and the Ross Sea.
- Spreading of deep waters (e.g., North Atlantic Deep Water (NADW) and Antarctic Bottom Water (AABW)), mainly as deep western boundary currents.
- Upwelling of deep waters: This is not as localized as convection and difficult to observe. It is thought to take place mainly in the Antarctic Circumpolar Current region, possibly aided by the wind (Ekman divergence; Figure 2).
- Near-surface currents: These are required to close the flow. In the Atlantic, the surface currents compensating the outflow of NADW range from the Benguela Current off South Africa via the Gulf Stream and the North Atlantic Current into the Nordic Seas off Scandinavia (Figure 3). It is worth noting that the Gulf Stream is primarily a wind-driven current, forming part of the subtropical gyre circulation. The THC – approximated here by the amount of water needed to compensate for the southward flow of NADW – contributes only approximately 20% to the Gulf Stream flow.

Some Observational Data

As explained previously, the THC is not a measurable quantity but, rather, a conceptual idea. However, even many aspects of the MOC are difficult to measure. The vertical motions of sinking and upwelling are too slow to directly capture with current meters. Surface currents are to a large extent part of wind-driven horizontal circulations, so measurements do not easily yield values for the surface component of the MOC. Deep western boundary currents, tracer data, and inverse calculations combining various data sources and physical constraints give the best information on the MOC (Figure 4).

Figure 1 Schematic representation of the global thermohaline circulation (THC). Surface currents are shown in red, deep waters in light blue, and bottom waters in dark blue. The main deep water formation sites are shown in orange. Modified from Broecker WS (1991) The great ocean conveyor. *Oceanography* 4: 79–89; Kuhlbrodt T, et al. (2007) On the driving processes of the oceanic meridional overturning circulation. *Reviews of Geophysics* 45: RG2001.

Figure 2 Side view of the circulation in the Atlantic showing various flow components and mechanisms discussed in the text. Color shading shows the observed density stratification, with lightest waters in blue and densest in orange. Reproduced from Kuhlbrodt T, et al. (2007) On the driving processes of the oceanic meridional overturning circulation. *Reviews of Geophysics* 45: RG2001.

The volume transport of the overturning circulation at 24°N in the Atlantic has been estimated from hydrographic section data (Roemmich and Wunsch, 1985) as 17 Sv ($1\text{ Sv} = 10^6\text{ m}^3\text{ s}^{-1}$) and its heat transport as 1.2 PW ($1\text{ PW} = 10^{15}\text{ W}$). Talley et al. (2003) estimated 18 ± 5 Sv of NADW formation, and an inverse model (Ganachaud and Wunsch, 2000) yielded 15 ± 2 Sv NADW overturning in the high latitudes.

Narrow channels provide a good opportunity to measure deep water flows. The overflows from the Nordic Seas have been measured as transporting ~ 3 Sv each between Greenland and Iceland and between Iceland and Scotland (Figure 5), whereas the deep water formation south of these sills, in the Labrador Sea, is estimated as 2–4 Sv. Combined, these numbers do not add up to the total NADW flow estimates given

previously because the volume transport of dense water increases through mixing along the way in a process called entrainment (at the expense of being diluted; i.e., the core density decreases).

Less information is available about the second major deep water formation region of the global oceans, namely the

Southern Ocean around Antarctica (Figures 6 and 7). Tracer data suggest another ~ 15 Sv of deep water forming there, bringing the global total to slightly more than 30 Sv. More recent chlorofluorocarbon data suggest only 5 Sv sinking from the surface around Antarctica, which may be reconciled either by a change over time or, more likely, again by entrainment.

What Drives the THC?

The simplest answer to this question would be high-latitude cooling. In cold regions the highest surface water densities are reached; this causes sinking of water, which in turn drives the circulation. This is a thermally dominated circulation in that it is the coldest waters that sink to fill the deep oceans, and for the moment we will ignore the effects of salinity, returning to them in section 'Nonlinear Behavior of the THC.'

Reality is more complex, however. Cooling a previously warmer ocean at the surface will lead to sinking of the coldest, densest water, which will spread out along the bottom causing upwelling elsewhere, according to what is termed 'filling box dynamics.' However, eventually (after ~ 1000 years at current deep water formation rates) the box would be full – the ocean basins would be filled with dense water and the 'filling box' circulation would come to a halt.

Maintaining a steady-state circulation thus requires more than cold high latitudes. It requires either the source water to get continually denser to keep replacing the water in the box (which contravenes the idea of a steady state) or a mechanism that continually works to make the water in the box less dense so that the source water remains denser than the water already in the box. This allows a steady state, with newly formed dense waters spreading in the ocean tending to increase the density while the other mechanism tends to reduce the

Figure 3 Circulation of the northern Atlantic and Arctic oceans. This simplified figure shows surface currents in red and North Atlantic Deep Water (NADW) in blue. The winter sea ice cover (white) is held back in the Atlantic sector by the warm North Atlantic Current. Figure modified for the Arctic by G. Holloway.

In: Skjoldal HR (ed.) *The Norwegian Sea Ecosystem*. Trondheim: Tapir Academic Press.

density. The flow field adjusts so that both processes are in equilibrium and the density field remains steady.

This basic constraint was understood by Sandström: He found that heating and cooling his tank at the surface could not drive a steady-state, deep overturning flow. Rather, heating at greater depth than cooling was required – a conclusion commonly known as Sandström’s theorem. This heating at depth is a mechanism that makes the deep waters continually less dense, allowing an ongoing replacement by colder water from above.

What is this mechanism in the real ocean, where heating occurs at (or very near) the surface due to the Sun? As Sandström speculated, it is the downward penetration of heat by mixing. The result is the classic advection–diffusion balance: In steady state, at any given point in the depths of the oceans, the slow diffusion of heat by turbulent mixing is balanced by the equally slow transport of cold waters from the poles.

Downward mixing of heat requires energy to overcome frictional dissipation and to raise the potential energy stored in the water column, as heat penetrating downward expands the deep water and lifts up the waters above. This is the energy supply of the THC: In an energetic sense, it is driven by turbulent mixing in the ocean’s interior. This is why mixing appears in the definition of THC given at the outset of this article (quoted from Rahmstorf, 2002).

The power supply of the turbulence that causes this mixing is both by tidal motions and by the winds. The energy supply

needed for generating the observed global overturning motion of ~ 30 Sv can be estimated from the advection–diffusion balance and the observed density field as ~ 0.4 TW (Munk and Wunsch, 1998). This can be compared with the power input by winds and tides, estimated as approximately 1 TW each, although these estimates are rather uncertain. With a mixing efficiency of 20%, 0.4 TW would be available for driving the THC (the remaining 80% is dissipated).

Although the energy supply of the THC thus ultimately comes from winds and tides, it is useful to keep the established term ‘thermohaline circulation’ (as we keep calling ‘steam engine’ a machine that is powered by coal or wood) in order to distinguish this driving mechanism from a completely different kind: the direct generation of large-scale currents by the frictional action of wind on the water surface. Apart from obviously driving surface currents, this mechanism could also be involved in driving the deep-reaching MOC, in a manner proposed by Toggweiler and Samuels (1995).

This mechanism works as follows: Westerly winds over the Southern Ocean, in conjunction with the Coriolis force, lead to a divergence of surface currents in this region and hence to upwelling. In contrast to the majority of the ocean, where wind-driven upwelling is confined to the upper ocean, the upwelling here comes from deep waters. The reason is a peculiar dynamic constraint on the rotating Earth, termed the ‘Drake Passage Effect’: Due to the lack of topographic barriers at the latitude band of Drake Passage, no east–west pressure

gradient and hence no meridional flow outside frictional boundary layers can be maintained there. This means that the surface water pushed north by the wind (northward Ekman transport resulting from westerly winds) can only be returned to the south at great depth, below 2500 m, where topographic features exist to support a southward flow. Toggweiler and Samuels (1995) argued that the downward branch required to connect the northward surface flow with this deep southward flow can only occur in the high-latitude north Atlantic because this is the region with the highest surface densities and stable stratification precludes deep water formation elsewhere. In this mechanism, the energy input occurs in the Southern Ocean through the wind creating an Ekman divergence at the surface and convergence at depth, directly 'lifting up' water there, with the MOC looping through the Atlantic to fulfill a continuity requirement.

Which of these two alternative mechanisms actually drives the observed MOC in the world oceans? This discussion is strangely reminiscent of the nineteenth-century debate on wind-driven versus convection currents. Recent literature suggests that both mechanisms play a role (a detailed discussion of the issues raised here and the observational evidence is found in the review article of Kuhlbrodt et al. (2007)). The MOC would thus be composed of both a thermohaline and a wind-driven component (Figure 8).

This view is supported by models: If wind forcing at the ocean surface is turned off in a standard climate model, eliminating the second mechanism, the MOC weakens somewhat but qualitatively remains the same. If interior mixing is reduced, weakening the first mechanism, then the MOC also weakens somewhat but then remains unchanged as one goes to extremely small mixing values. Thus, either mechanism is apparently capable of driving a MOC not unlike that observed. Determining which of them dominates in the real ocean requires further study.

It should be noted that these considerations apply to the mechanism for driving a long-term steady flow, not to the transient response to rapid thermohaline forcing such as a big meltwater inflow (discussed later). The mechanism for interrupting the flow by a density perturbation is different from the driving mechanism; the latter will only come into play on longer timescales.

Right: Wind-driven circulation through the 'Drake Passage' effect. Reproduced from Kuhlbrodt T, et al. (2007) On the driving processes of the oceanic meridional overturning circulation. *Reviews of Geophysics* 45: RG2001.

Nonlinear Behavior of the THC

The highest surface densities in the oceans are reached where water is very cold, whereas lower densities are found in the saltier but warmer tropical and subtropical areas. The THC is thus thermally driven. Nevertheless, the influence of salinity is important and gives rise to an interesting nonlinearity of the system.

Defant's (1929) textbook discussed the fact that cooling and freshwater input have an opposing effect on density in the northern Atlantic and, hence, on the THC. This results in a bistability of the system, first described in a classic paper by Stommel (1961) with the help of a simple box model. Salinity is involved in a positive feedback: Higher salinity in the deep water formation area enhances the circulation, and the circulation in turn transports higher salinity waters into the deep water formation regions (because these are regions where precipitation exceeds evaporation, freshwater would accumulate and surface salinity would drop if the circulation stopped). In Stommel's model the high-latitude salinity increases linearly with the flow, and the flow increases linearly with high-latitude salinity, which combined results in a quadratic equation for the flow as function of freshwater input. This leads to two possible equilibrium states: The system is bistable in a certain parameter range.

The situation can be described with a simple stability diagram showing strength of the MOC as a function of the freshwater input into the North Atlantic. Figure 9 shows the bistable regime and a bifurcation point S, where the circulation breaks down. If freshwater input to the northern Atlantic is systematically increased and decreased, a hysteresis loop between transitions a and d results. This hysteresis behavior appears to be a

Figure 9 Schematic stability diagram for the Atlantic THC, with solid black lines indicating stable equilibrium states and dotted black lines unstable states. Transitions are indicated by arrows: (a) advective spindown, (b) convective shutdown, (c) transition between different convection patterns, and (d) restart of convection. 'S' marks the Stommel bifurcation beyond which no NADW formation can be sustained. Adapted from Rahmstorf S (2000) The thermohaline ocean circulation – A system with dangerous thresholds? *Climatic Change* 46: 247–256.

robust feature that has been found in many different climate models (Figure 10; Rahmstorf et al., 2005). Although all models tested in this study show qualitatively similar hysteresis behavior, only some have their present-day climate residing in the bistable parameter regime. Whether the real climate system is bistable is unknown.

The salt transport feedback is not the only feedback rendering the system nonlinear. The convective mixing process is itself a highly nonlinear, self-sustaining process. In models this leads to multiple stable convection patterns. On the one hand, this can cause artifacts related to the coarse model grid; on the other hand, this may be part of a real mechanism for shifts in convection location, as have apparently occurred during glacial times.

The Circulation's Effect on Climate

The climatic effect of the MOC is due to its large heat transport of up to 1 PW in the North Atlantic. Back-of-the-envelope calculations suggest that this amount of heat transported into the northern North Atlantic (north of 24° N) should warm this

Figure 10 Hysteresis curves from a range of different intermediate-complexity climate models including three-dimensional ocean models. The curves are derived by slowly increasing the freshwater influx to the north Atlantic, then decreasing it again, from a present-day initial state of each model marked by an open circle. region by ~ 5 K. This is indeed approximately the difference between sea surface temperature in the North Atlantic compared to the North Pacific at similar latitudes. An examination of sea ice margins suggests that they are pushed back by the warm surface currents in the Atlantic sector compared to the North Pacific (Figure 3), which in turn leads to reduced reflection of sunlight and thus warming (albedo feedback). Examination of observed surface air temperatures is suggestive (Figure 11): Over the three main deep water formation regions of the global oceans, air temperatures are warmer by up to $\sim 10^\circ\text{C}$ compared to the latitudinal mean. These observations, however, are no quantitative proof of the climatic effect of the THC, and other explanations can be partly invoked, such as planetary waves in the atmosphere that are locked in place by the geography.

One way to estimate the effect of the THC is to switch off NADW formation in coupled climate models (by adding a large freshwater anomaly to the northern Atlantic). Roughly, this leads to a cooling with a maximum of typically ~ 10 K over the Nordic Seas (Figure 12). The maximum tends to occur near the sea ice margin due to the positive ice albedo feedback, which causes air temperatures to cool much more than sea surface temperatures. The amplitude and spatial extent of the cooling are somewhat model dependent. Most models tend to cool temperatures over land in northwestern Europe (Scandinavia and Britain) by a few degrees, and some show strong cooling further west affecting Canada.

In models the Northern Hemisphere cools and the Southern Hemisphere warms if the THC is brought to a halt because the cross-equatorial heat transport in the ocean is reduced. This change in heat partitioning between the two hemispheres shifts the thermal equator to the south and thus the intertropical convergence zone (ITCZ) and the associated tropical rainfall belts. This is a robust phenomenon seen in models and consistent with paleoclimatic data.

Finally, a change in circulation also leads to a change in sea level. Currently, sea level in the northern Atlantic is almost 1 m lower than in comparable parts of the North Pacific because deep water forms only in the former. This is due to the geostrophic balance of surface currents and sea surface slopes. Any change in surface currents is associated with a rapid dynamic adjustment of the sea surface topography (with no effect on the global average sea level); in case of a shutdown of NADW formation, the sea level around the northern Atlantic would

Figure 11 Deviation of surface air temperature from zonal mean ($^\circ\text{C}$). Reproduced from Rahmstorf S (2000) The thermohaline ocean circulation – A system with dangerous thresholds? *Climatic Change* 46: 247–256.

quickly rise by up to 1 m (Figure 13). A further, slower and global sea-level response would result as the deep ocean temperature changes.

The Role of the THC in Quaternary Climate Changes

Sediment data document that the THC has undergone major changes in the Quaternary (Clark et al., 2002; Rahmstorf, 2002). Three major circulation modes were identified: a warm mode similar to the present-day Atlantic, a cold mode with NADW forming south of Iceland in the Irminger Sea, and a switched-off mode without significant formation of NADW (Figure 14). The latter appears to have occurred after major input of freshwater, either from surging glacial ice sheets (Heinrich events) or in the form of meltwater floods (e.g., Younger Dryas event). The most dramatic climate events recorded in Greenland, the Dansgaard-Oeschger (DO) events, could be explained by north-south shifts in convection location (i.e., transitions between warm and cold modes of the Atlantic THC). The coincidence of changes in ocean circulation and in surface climate, as well as the climate effects and stability properties of the THC discussed previously, suggest that ocean circulation changes can play a key dynamical role in abrupt glacial climate change. Proxy data show that the South Atlantic cooled when the north warmed and vice versa, a

see-saw of Northern and Southern Hemisphere temperatures that is indicative of an ocean heat transport change.

Heinrich events are thought to result from ice sheet instability: An episodic iceberg discharge would have provided a large freshwater addition of the order of 0.1 Sv to the Atlantic for several centuries (Roche et al., 2004). Models suggest this could have been enough to stop all NADW formation due to the reduced density of ocean surface waters; this in turn would explain the cooling found in proxy data, especially around the midlatitude Atlantic. In Greenland, Heinrich events appear to have had little effect, presumably because they occurred during cold phases (cold mode, Figure 14) when the THC already did not reach far enough north to warm Greenland climate.

DO events are dramatic warm events with a large amplitude in Greenland (8–16 °C within approximately a decade; Severinghaus et al., 2003) and areas surrounding the northern Atlantic. A large coinciding increase in salinity in the Irminger Sea suggests a northward push of warm, salty Atlantic waters into the Nordic Seas (Krevelde et al., 2000), which could explain the large warming. What triggered these ocean circulation changes is unknown. Data analysis and modeling have suggested the intriguing possibility that stochastic resonance may have played a role (Alley et al., 2001). This is a physical mechanism that can lead to threshold transitions in systems forced by a weak regular forcing (e.g., a solar cycle) and stochastic variability.

Figure 13 Dynamic sea-level change in a model experiment in which NADW formation was shut down. The global mean of this sea-level change is zero; any global mean sea-level changes resulting from the changed climate occur in addition to the shown redistribution of mass. Reproduced from [Levermann A, et al. \(2005\)](#) Dynamic sea level changes following changes in the thermohaline circulation. *Climate Dynamics* 24: 347–354.

Figure 14 Schematic of three circulation modes of the glacial Atlantic: the prevailing cold mode (middle), the warm mode associated with Dansgaard–Oeschger events (bottom), and the ‘off’ mode occurring after Heinrich events (top).

The role of ocean circulation changes on longer timescales (i.e., for the glacial–interglacial cycles) is still under discussion. Reconstructions of the rate of deep water formation and MOC during glacial times are still tentative but are consistent with prevailing roughly similar, perhaps somewhat weaker overturning rates compared to those in modern times (except during events). Models run for glacial conditions also suggest similar or somewhat weaker overturning rates ([Figure 15](#)) (although a few indicate moderate strengthening). More important for climate than the rate of overturning is the latitude at which deep water forms. Data and some models indicate a southward shift of the main deep water formation sites from the Nordic Seas to a location south of Iceland, which implies a reduced ocean heat transport into high latitudes and an expansion of sea ice. Models suggest that these factors may have amplified glacial cooling, although ocean circulation changes are probably not a crucial factor for glacial inception.

During deglaciation, melting ice sheets surrounding the North Atlantic have apparently led to episodic influx of meltwater into the ocean. The effect of this meltwater on the THC may explain the oscillations and abrupt cold reversals seen, for example, in Greenland ice cores during this time, including the Younger Dryas and the 8 K cold events. This contrasts with the much smoother history of deglaciation found in Antarctic ice cores.

The Future of the THC

Global warming can affect the THC in two ways: surface warming and surface freshening, both reducing the density of high-latitude surface waters and thus inhibiting deep water formation. Most models predict a significant weakening of

Figure 15 Circulation of modern and glacial Atlantic, as reconstructed by ^{13}C tracer data (left; reproduced from Duplessy J-C, et al. (1988) Deep water source variations during the last climatic cycle and their impact on the global deep water circulation. *Paleoceanography* 3: 343–360) and from a model simulation (right; reproduced from Ganopolski A, et al. (1998) Simulation of modern and glacial climates with a coupled global model of intermediate complexity. *Nature* 391: 351–356). Note the shallower flow of NADW and the upward and northward expansion of AABW (darker blue) in glacial times, as well as the southward shift of deep water formation in this model.

NADW formation (by 20–50%) in response to anthropogenic global warming during the twenty-first century (Intergovernmental Panel on Climate Change, 2001). Some also find a reduction in AABW formation.

These models did not include meltwater runoff from the Greenland ice sheet, which is difficult to predict. A melting of the ice sheet during 1000 years would imply an average meltwater influx of ~ 0.1 Sv, similar to that estimated for Heinrich events. Hence, the future evolution of the Atlantic THC is probably closely tied to the fate of the Greenland ice sheet.

Model simulations – even those that lead to a complete shutdown in the future – find that the influence of anthropogenic warming on the THC until today should be smaller than the natural variability. Therefore, any variations observed to this date are likely related to natural oscillations. However, observations indicate a widespread freshening trend in the northern Atlantic, which, should it continue, could contribute to a future weakening of the THC in the Atlantic (Curry and Mauritzen, 2005).

A major weakening or shutdown of NADW formation could have serious impacts on marine ecosystems, sea level, and surface climate, including a shift in ITCZ and tropical rainfall belts. A THC collapse is widely discussed as one of a number of ‘low probability–high impact’ risks associated with global warming.

Volcanic and Solar Forcing

Solar Variability

Prior to large-scale industrialization, climate forcing was primarily due to natural variations in the Sun's output and in volcanic eruptions for timescales up to several thousand years. The Sun also plays a role in orbital forcing, which is driven by changes in the relative position and orientation of the Earth with respect to the Sun (rather than changes in the output of the Sun). The systematic variations in the Earth's precession, obliquity, and eccentricity create three distinct cycles (Milankovitch cycles) that combine to determine the orbital forcing. Summer insolation reaching northern middle latitudes, which plays a major role in ice-sheet growth and retreat, is highly correlated at long timescales ($>20,000$ years) with long-term climate including glacial–interglacial transitions. This orbital forcing is distinct from solar forcing, which refers instead to variations in the irradiance output from the Sun. Over long timescales for which orbital forcing is substantial, solar and volcanic forcing are thought to be comparatively much smaller and are therefore usually neglected.

Solar forcing takes place because the Sun's output varies on many timescales. Some of the most distinct are the 27-day rotation period of the Sun and the approximately 11-year solar cycle (or Schwabe cycle), also called the sunspot cycle and corresponding to half the 22-year cycle of the Sun's magnetic field. A longer cycle of approximately 80 years, called the Gleissberg cycle, modulates both the amplitude and the length of the sunspot cycle. It is difficult to measure the Sun's output precisely from the Earth's surface due to interference in the atmosphere from clouds and particulate, for example. Precise measurements have been obtained from satellites since 1979, and these clearly show variations up through the ~ 11 -year cycle, over which output varies by approximately 0.1% (Fröhlich and Lean, 2004; Willson and Mordvinov, 2003). However, temporal gaps between instrumental records make estimates of longer term changes difficult.

It is clear from the satellite observations that irradiance variations are not uniform across the spectrum, with variations over the ~ 11 -year solar cycle increasing from slightly $<0.1\%$ in the visible to 1–10% in the ultraviolet (UV) and shorter wavelengths. Although the Sun's output at these wavelengths is much less than in the visible, the larger percentage changes still imply that a substantial fraction of the integrated energy variations (~ 15 –20%) takes place at these wavelengths. This radiation is largely absorbed by oxygen and ozone before reaching the Earth's surface, or even the troposphere. However, it has the potential to alter the climate and composition of the stratosphere and above. In particular, UV radiation can produce ozone when it is absorbed by an oxygen molecule in the stratosphere so that increased UV irradiance leads to an increase in stratospheric ozone. This phenomenon has been recorded in both satellite and ground-based ozone data. The

altered ozone as well as the altered irradiance both affect stratospheric temperatures, primarily in sunlit regions, leading to changes in circulation that could in principle affect surface climate. Thus, it is important to know not only how total solar irradiance has varied but also how that variability has depended on wavelength. Unfortunately, even less information is available about past variations in the solar spectrum than the limited 1979–present total irradiance data set, and proxies offer little promise of reconstructing the spectral variation of past irradiance changes.

Some longer term data that appear to be related to total solar output are available. Sunspots records extend back to the seventeenth century, and the modern satellite data confirm that sunspots are highly correlated with irradiance over ~ 11 -year solar cycles. The correlation is an inverse one because the dark sunspots are accompanied by bright regions called faculae during periods of high solar activity, and the faculae exert a stronger influence on total solar output. However, exactly how the sunspot number, a value related to both the number of individual spots and the number of sunspot groups, is related to solar output is unclear. Even more confounding is that there is no good evidence as to whether additional changes in solar output that are not reflected in sunspots took place in periods such as the Maunder Minimum from approximately 1650 to 1710, during which very few sunspots were observed. If the Sun was simply in an extended minimum comparable to that seen in the ~ 11 -year solar cycle, then the reduction in irradiance relative to the mean value in typical cycling conditions would be only one half of one solar cycle's variations, or approximately 0.05%. Many estimates during the past several decades have put the value between several times to more than an order of magnitude greater than this under the assumption that other long-term 'background' changes also took place (Lean, 2000). These were often based on astronomical comparisons with other 'Sun-like' stars, which are now regarded as fairly poor analogs to our own Sun, and recent estimates tend to find substantially reduced long-term solar variations (e.g., Foukal et al., 2004).

Other proxy data have also been used to infer past solar output. The cosmogenic proxies ^{10}Be from ice cores and ^{14}C from tree rings have both been used to reconstruct historical irradiance (Stuiver and Braziunas, 1989). Both isotopes are produced by galactic cosmic rays striking the Earth's atmosphere. The flux of these rays reaching the Earth is modulated by the strength of the solar magnetic field, causing cosmogenic isotope production to vary inversely with solar output. Records of both isotopes show periodicities at many scales, and ^{10}Be , the higher resolution of the two, captures the ~ 11 -year solar cycle reasonably well. Both proxies show periods of extensive lows, of which the Wolf (~ 1280 – 1350), Spörer (~ 1450 – 1540), and Maunder Minima (~ 1645 – 1715) are the most prominent during the past millennium. However,

an absolute calibration of these proxies remains elusive because neither the precise relationship between solar output and the solar magnetic field (and hence isotope production) nor the confounding influence of other factors, such as climate change altering the transport of proxies and their deposition onto ice sheets, are well characterized. Nevertheless, the cosmogenic proxies appear to be reasonably good indicators of when solar irradiance varied despite their limited use in determining the magnitude of such variations. It has been suggested that these proxies show that the Sun is now at its brightest level in many millennia, but further research has demonstrated that this inference appears to result from a flawed calibration technique used in the initial analysis. Thus, the various proxy data sets do not provide a reliable estimate of solar variability during the Quaternary. From the solar physics side, although there has been much progress in helioseismometry (the study of the internal oscillations of the Sun) in recent decades, solar models are still in the early stages of development. Although they have made some notable progress (Wang et al., 2005), they are not able to reproduce some of the known features of the solar dynamo or to spontaneously enter a noncycling state such as the Maunder Minimum. Thus, it is not possible to reliably estimate the precise magnitude of past solar irradiance changes, even for the past two decades, although the time dependence of these changes is known fairly accurately.

Volcanism

The other main natural forcing of climate at timescales of thousands of years or fewer is volcanism. As with solar variability, modern measurements of the optical properties of volcanic aerosols injected into the atmosphere have been available only for the past several decades, with the 1991 eruptions of Mount Pinatubo in the Philippines being by far the best observed. However, reliable optical data on volcanic aerosols (particulate) injected into the upper atmosphere extend back considerably farther than for solar irradiance (Sato et al., 1993) because the observations are technically much simpler due to a much larger signal-to-noise ratio. Prior to the direct optical measurements, a range of historical, geological, and proxy data are used to estimate explosive volcanism. Documentary evidence recording the location of large eruptions has been available for the past several centuries. Geologic evidence allows volcanologists to estimate the explosivity of eruptions, from which the volume of material ejected into the atmosphere can be estimated. One of the most useful techniques is using particulates found in polar ice cores to reconstruct past volcanism. The technique relies on the presence of ash layers in ice cores from the same years in both Greenland and Antarctica, which then implies an eruption with a worldwide impact (Crowley, 2000). In practice, one is more confident if the ash layer can be related to a large, known eruption so that the coincidental eruption of two high-latitude volcanoes near the ice core locations can be ruled out. Since Greenland receives ash from nearby Iceland quite frequently, such a coincidence is not as unlikely as it might seem. Chemical analysis of the ash could also definitively link the ash layers from the two poles, but it is expensive and difficult. Most important, the thickness of the ash layer must then be used to estimate the global impact

of the volcanic aerosols on the Earth's radiation budget (the forcings), an inherently challenging task with substantial uncertainties. Thus, as with solar forcing, the timing of past volcanic forcing is much better known than its magnitude. The records derived from ice cores can be calibrated against modern optical measurements during the period of overlap, however, giving us reasonable confidence in the magnitude of volcanic forcing for at least the past several centuries.

To affect climate, eruptions typically have to inject material into the tropical stratosphere, from which it can be distributed worldwide within a year or two at most. Eruptions that deposit material only in the troposphere usually do not noticeably perturb the global mean climate because the material affects only a portion of the globe and is rapidly removed by the hydrologic cycle. Volcanic aerosols, from eruptions that inject material into the stratosphere but occur poleward of the two subtropical jet streams located at approximately 30° latitude, typically spread out closer toward the pole but not into the tropics or the other hemisphere, and thus seem to have much less global impact. Volcanic aerosols are removed from the stratosphere with an exponential decay time of approximately 1.5–2 years so that a large tropical eruption typically affects climate for 1–3 years. Catalogs of known eruptions now document thousands of events (Simkin and Siebert, 1994). The largest eruption in the past 500 years was that of Tambora in Indonesia during 1815, which caused the famous 'year without a summer' the following year. The largest eruption during the past millennium took place in 1259, but its location has not been determined. In the more distant past, supereruptions such as the Toba eruption ~75 000 years ago (in Indonesia) may have had a major impact on climate. Proxy evidence for the period following Toba's eruption, for example, suggests that it coincided with a cooling epoch lasting ~1000 years, although the connection with volcanism is not firmly established. Similarly, extended periods of enhanced volcanic emissions such as those that created the Deccan or Siberian Traps could have induced climate change by increasing tropospheric aerosols for millennia.

Climate Modeling

The climate impact of solar and volcanic forcing can be investigated by a combination of data analysis and modeling studies. Given an estimate of either solar or volcanic forcing – that is, how the radiative balance of the Earth was changed – a climate model can be used to examine the magnitude, pattern, and timing of the climate response and to explore the underlying physical mechanisms that drive it. These models, of varying complexity, include mathematical representation of features of the climate system, such as the land, oceans, atmosphere, and cryosphere, and the physical, chemical, and biological processes in those regions that affect climate. Energy balance models (EBMs) compute the surface temperature response using a one-dimensional column calculation of changes in incoming and outgoing radiation in response to external forcing. Although simple, these models can tell us much about the global mean annual average response (Crowley, 2000). It is clear from these studies, for example, that volcanic eruptions are the primary cause of externally

forced interannual variations in global mean annual average surface temperature. To fully understand the response of the climate system, however, requires the use of a three-dimensional general circulation model (GCM). These models generate their own inherent variability due to nonlinear chaotic interactions in the highly coupled climate system, which are referred to as internal or unforced variability. This unforced variability provides a baseline against which the response to forcings from outside the climate system, such as solar variations, volcanic eruptions, or greenhouse gases, can be compared. Investigations with these models provide information on the spatial pattern and timing of the climate response to external forcing as well as its magnitude. Studies with state-of-the-art GCMs are limited by available computer power but have advanced dramatically during recent decades. Simulations with GCMs can be compared with observations or proxy data for a wide range of spatial and temporal scales, and the model response can be analyzed to determine the most important processes at work in a particular case. Such comparisons are discussed next.

Proxy Data

The role of solar and volcanic forcing in climate change during the Holocene has been studied more than any other period during the Quaternary. One reason for this is that climate data covering much of the globe are more widely available, especially for the past 1000 years. This allows the proxy data to be compared with estimates of past solar and volcanic forcing, and correlations between the proxy climate records and the forcings can then be compared with the results from climate models used to examine the response to these forcings. Proxies with high temporal resolution, typically from decadal to annual or even seasonal resolution, are generally best for comparison with model simulations. Comparisons for the past millennium can be made with reconstructions of surface temperatures based on networks of proxy data. Of these, tree rings are the most abundant proxy. The width and density of tree rings are related to summer temperatures, and these records can be accurately dated to individual years. Ice core oxygen-18 isotopic ratios also serve as a temperature proxy. These extend back to nearly 1 Ma, making them one of the oldest high-resolution proxies. In sites with high snow accumulation rates, annual temperatures can be retrieved. The limitations of this proxy are primarily that ice cores are restricted largely to the polar regions, and assigning temperatures to calendar years has significant uncertainty. Coral growth rates help fill in the spatial gaps of the ice core records by providing information from the tropics. Documentary evidence is another useful source for the past millennium. Like tree rings, it can be matched exactly with calendar years; however, it is restricted primarily to Europe and East Asia. Annual layers of lake sediments (varves) and annual accumulation in stalagmites (speleotherms) are additional proxies. Finally, deep ocean sediment cores extend farther back in time than any other source, although their interpretation is less straightforward and dating is more uncertain than for the other sources. Additionally, because the ocean integrates transport, temperature, and salinity changes over large spatial and temporal scales, these data typically cannot provide information about the response to

short-term perturbations such as volcanism. During the past millennium, data are plentiful enough that multiple data sets can be combined, allowing reconstructions to be developed for this period with confidence in both the global or hemispheric average temperature changes and the spatial patterns (Jones and Mann, 2004). This is not the case further back in time. However, additional proxy records such as pollen can give a qualitative sense of ancient warm or cool periods over middle latitude continental areas that complements the high-latitude ice core and the oceanic sediment core records.

Model/Data Comparisons

The proxy temperatures clearly show the effects of large eruptions such as Huaynaputina in 1600 or Parker in 1641 (Figure 1), or the later large eruptions of Tambora in 1815 or Krakatua in 1883. In general, these are consistent with the direct observations of the response to recent eruptions such as Pinatubo in 1991. GCM simulations have reproduced the magnitude, spatial pattern, and timing of surface temperature changes in response to the Pinatubo eruption (Robock, 2000; Shindell et al., 2004). Analysis of a large number of eruptions during the past millennium, which improves the statistical reliability of the results, shows a distinct pattern of Northern Hemisphere wintertime warming over the northern continents and cooling over the Labrador Sea region and in the Middle East (Robock, 2000; Shindell et al., 2004). This pattern represents a shift toward the positive phase of the dominant naturally occurring mode of Northern Hemisphere extratropical variability, the large-scale pattern known as either the Northern Annular Mode (NAM) or the Arctic Oscillation (AO). This pattern is closely related to the more regional North Atlantic Oscillation so that in the Atlantic sector they are extremely similar. The hemispheric-scale NAM/AO pattern is visible from the surface up into the stratosphere, however, making it a logical choice for describing the response to solar and volcanic forcing because these have their greatest direct impact on the stratosphere. The relatively good agreement between models and observations in the modulation of the NAM/AO and the resulting Northern Hemisphere continental winter warming following large tropical eruptions is shown in Figure 2. The model result shown in the figure is typical of current GCMs that incorporate the stratosphere (where the volcanic aerosols are injected, but a region often left out of climate models used mainly for other types of studies). It shows the best match between the model and the historical data over Eurasia and the Labrador Sea region, both of which are locations where variations in the NAM/AO have a strong influence on surface temperatures. The response over North America is more difficult to simulate or to determine from data because several of the largest recent eruptions coincided with a strong positive phase in the El Niño/Southern Oscillation (ENSO), which has a strong impact in this region. It is a subject of debate as to whether there is a causal link between volcanic eruptions and ENSO events. The winter continental warming response persists with a similar spatial structure into the second winter following large tropical eruptions but has largely faded away by the third.

Proxy data generally show cooler hemispheric-scale temperatures during solar minima, although the magnitude varies

Figure 1 Comparisons between Northern Hemisphere surface temperature anomalies from a proxy reconstruction and a general circulation model (GCM). The proxy reconstruction (Mann et al., 1999) (thick black line) includes an estimate of uncertainty (thin lines bracketing the thick black line), whereas the model results show the mean of six model runs (purple). Large volcanic eruptions included in forcing of the model are marked with triangles, and the response to some of these events is clearly seen in both the model and the proxy data. Adapted from Schmidt GA, Shindell DT, Miller RL, Mann ME, and Rind D (2004) General circulation modelling of Holocene climate variability. *Quaternary Science Review* 23: 2167–2181.

Figure 2 Surface temperature anomalies (°C) during the cold season (October–March) following large tropical volcanic eruptions from proxy reconstructions (top) and in a GCM (bottom). The proxy data are averages of the response to 11 large, well-identified historical eruptions. The model results are the mean cold-season response to 15 simulated eruptions with similar magnitudes to those in the historical analysis. Hatching indicates areas where the response is significant at the 95% confidence level. Modified from Shindell DT, Schmidt GA, Mann ME, and Faluvegi G (2004) Dynamic winter climate response to large tropical volcanic eruptions since 1600. *Journal of Geophysical Research* 109: D05104.

between different reconstructions. EBMs can reproduce the general changes, but given that the magnitude of the changes and the solar forcing are both uncertain, this is not a powerful constraint. GCMs face the same uncertainties in matching global or hemispheric changes. There are two primary ways

around this problem, namely examining the time dependence of climate change in comparison with forcings or examining the spatial pattern of the climate response. In both cases, the importance of uncertainties in the exact magnitude of forcing and response is minimized.

Climate modeling at the NASA Goddard Institute for Space Studies (GISS) examined the global and regional response to volcanic eruptions and solar variability using the GISS climate model. The results were then compared with reconstructions of surface temperatures from historical times, focusing on the change between the late seventeenth and eighteenth centuries. The late seventeenth century, coinciding with the Maunder Minimum, was one of the coldest parts of the period known as the 'Little Ice Age,' when hemispheric average temperatures dropped by a few tenths of a degree. Both reduced solar output and numerous large volcanic eruptions could have contributed to the hemisphere-wide cooling. Regional changes were much larger, however. Europe and eastern North America, for example, were unusually cold, whereas some other areas appear to have been relatively warm.

In the climate model, both the reduced output from the Sun and the increased amount of the volcanic aerosol particles that reflect sunlight away from the Earth contributed a sizeable amount to the Northern Hemisphere cooling seen in temperature reconstructions (Schmidt et al., 2004; Shindell et al., 2003). Their relative importance depends on uncertain estimates of exactly how much each changed relative to a century later. The global or hemispheric average GCM values are quite similar to those obtained in EBM studies (Crowley, 2000).

Regionally, however, solar forcing appears to have played the dominant role in driving annual average temperature changes over periods longer than a year or two (Figure 3). Multiple factors account for this difference. Volcanoes have a major effect on circulation of the atmosphere for a year or two, as discussed previously, but the aerosols fall fairly rapidly out of the atmosphere, resulting in little long-term effect. Furthermore, the effect during the first and second years following eruptions is to increase westerly airflow around the Northern Hemisphere during winter, when circulation responds most strongly to the latitudinal temperature gradients induced by the volcanic aerosols in the lower stratosphere. This enhanced flow brings relatively warm oceanic air over the continents, leading to the continental winter warming shown in Figure 2. In contrast, during the summer, volcanic aerosols lead to cooling via their reflection of sunlight, and this is strongest over the continents, and during summer the volcanic aerosols induce little change in circulation. The regional effects of eruptions during the cold and warm seasons thus tend to cancel one another, leading to a fairly uniform annual average response (Figure 3).

In contrast, the effects of reduced solar output are sustained, lasting for decades, and they also have similar impacts in all seasons. Decreases in solar output lead to reduced heating in the sunlit portion of the stratosphere due to the reduced UV radiation and reduced stratospheric ozone, and ensuing decrease in the meridional gradient of temperature causes decreased wintertime westerly wind flow. This results in less advection of relatively warm maritime air and hence colder Northern Hemisphere continental temperatures (the opposite of the effect following a large tropical eruption) (Shindell et al., 2001). This cooling is reinforced by cooler temperatures everywhere in the summer due to the reduced solar energy, but the land, having a lower heat storage capacity, responds more than the oceans. Thus, during both seasons the land cools in response to reduced solar irradiance, leading to a large regional annual average response.

Figure 3 Annual average surface temperature response ($^{\circ}\text{C}$) to decreased solar irradiance (top), substantial volcanic activity (second row), and both forcings (third row) in a GCM. The solar output reduction used in these simulations with the GISS GCM was approximately -0.3 W m^{-2} , whereas the mean volcanic forcing was approximately -0.4 W m^{-2} . Details of the simulations can be found in Shindell et al. (2003). For comparison, the difference between proxy temperature reconstructions averaged over 1680–1710 relative to 1780–1800 is also shown (bottom row). The 1680–1710 period, during the late Maunder Minimum, was a time with both reduced solar irradiance and enhanced volcanic activity relative to a century later.

In the GCM simulations, the annual average response to solar forcing resembles the observations much more closely than the response to volcanic forcing (Figure 3). The response is overall too strong, however, which may indicate an overestimate of how much the Sun dimmed during the late 1600s, an oversensitive model, or both. Nevertheless, it is clear that solar variability seems much more likely to have driven the large regional climate changes seen in historical data. This provides both a useful test of the ability of climate models to simulate patterns of regional changes and important evidence for the importance of solar variability in climate change.

Other modeling studies have demonstrated that the variability in global or hemispheric temperatures induced by volcanic eruptions is fairly well correlated with interannual

variations in the proxy reconstructions. However, at timescales greater than a century, volcanic eruptions are only very weakly correlated with the proxy data, whereas solar irradiance variations are highly correlated. This supports the conclusion that solar changes drive much of the multidecadal and longer variations in Quaternary climate, whereas volcanism is most important at shorter timescales. Further evidence for the role of the Sun in pacing millennial timescale variations in climate comes from records of ocean sediments (Bond et al., 2001) and lake sediments (Hu et al., 2003). These show significant correlations between climate proxy indicators and the solar-related cosmogenic proxies. However, the precise relationship between some of these proxies and climate is unclear, and an understanding of the physical mechanisms underlying such millennial scale interactions between the Sun and climate is lacking.

Introduction

The holistic assessment of the character and distribution of glacial sediments and landforms over whole drainage basins or even whole continents facilitates the reconstruction of glacier and ice-sheet dynamics over complete glacial cycles. The accuracy of such paleoglaciological reconstructions relies on analogs with modern examples. Increasing numbers and varieties of modern glacial landsystems are emerging in the research literature based on intensive studies of glacier processes and forms, and these can be utilized by Quaternary scientists interested in paleoenvironmental reconstruction but not specializing in glacial geology. Although paleoglaciological reconstructions are often difficult and sometimes controversial, significant developments in interpreting ancient glaciated landscapes have highlighted complex but coherent patterns of glacier activity over much of the last glacial cycle, and this is now increasingly being linked with regional and global climatic and oceanographic changes. Information on specific glacial processes and their products are reviewed elsewhere in this encyclopedia. This article focuses on basin-wide glacial depositional environments, incorporating interrelated process–form domains in sediment–landform associations that are characteristic of particular topographic and environmental settings or landsystems.

The Subglacial Environment

Ice-Sheet and Glacier Beds

Ice-sheet and glacier beds, rather than being areas devoid of long-term geomorphic records, are actually rich in evidence of ice buildup as well as recession. Large parts of the areas occupied by the former Pleistocene ice sheets are, in effect, fossil

glacier beds, providing a window into subglacial processes and environments that are only poorly known from modern examples, although recent discoveries of landform generation at the base of the Antarctic Ice Sheet are improving the understanding of process–form relationships at the ice–bed interface (e.g., [King et al., 2007, 2009](#)). Regional studies of former glacier beds have shown that the great ice sheets were highly dynamic entities with complex histories of advance and retreat, ice-divide migration, and internal dynamics, and that they shifted their configuration to adapt to climatic change, the position and depth of proglacial water bodies, and basal conditions (e.g., [Boulton and Clark, 1990](#); [Clark, 1993, 1999](#); [Dyke and Prest, 1987](#)). Even former ice streams have been identified in the subglacial bedform record ([Clark and Stokes, 2003](#); [Stokes et al., 2005](#)). With respect to the sedimentary record on former glacier beds, large-scale patterns of ice flow and subglacial conditions may be preserved in the form of distinct till units, glacitectonic deformation, and surfaces of erosion or non-deposition. Assemblages of subglacial deposits and landforms created during the advance and retreat of an ice sheet are typically very complex and often defy analysis by the traditional methods of sedimentary stratigraphy. The products of several glacial advances may be superimposed, and glacitectonic dislocation and subglacial deformation often rework all or part of any preexisting glacial and nonglacial strata. Owing to partial erosion or patchy deposition, tills relating to any one glaciation can be discontinuous so that individual events are only recognizable through the type, style, and orientation of glacitectonic structures.

Theoretical patterns of subglacial deposition and erosion created during an ice-sheet advance and retreat cycle are presented by [Boulton \(1996a\)](#). His model assumes that debris transport below a simple ice sheet occurs entirely by subsole

Figure 1 A typical model run from Boulton (1996a), showing subglacial debris transport in a time–space diagram. The ice sheet is initiated at a nucleation point at time $t=0$, and expands to the north and south, reaching its maximum 12 ka after inception. It then contracts into the area where it first developed, finally vanishing at $t=24$ ka. The model predicts that there will be an outer zone of deposition near the ice-sheet margin and an inner zone of erosion, although there will be no erosion below the ice divide where the balance velocity is zero. Reprinted from the *Journal of Glaciology* with permission of the International Glaciological Society.

deformation at rates scaled to the balance velocity of the ice sheet. Although this highly simplified model does not deal explicitly with other important subglacial processes such as the erosion of hard substrata, the entrainment of debris into basal ice layers, and deposition by lodgement and melt-out, it does provide interesting insights into large-scale time-transgressive patterns of erosion and deposition (Figure 1). The model predicts an outer zone of deposition near the ice-sheet margin and an inner zone of erosion, which gives way to a zone of no erosion below the ice divide. The history of deposition and erosion at any given site reflects the migration of the depositional and erosional zones during ice-sheet advance and retreat. At each site, deposition will occur during ice-sheet advance. The resulting till will be removed from most sites by the subsequent erosion phase, although it will be preserved near the ice-sheet limit. As the ice-sheet retreats, the zone of deposition passes over each site in turn, depositing a retreat-phase till. After final deglaciation, the overall pattern of deposition and erosion comprises four major zones: Zone 1 – the ice-divide zone, with slight erosion due to ice-divide migration

and a thin till deposited during the retreat phase (sites E and F); Zone 2 – a zone of strong erosion, in which the advance-phase till and part of the preglacial substratum are removed (the erosion surface is capped by the retreat-phase till (sites B, C, D, G, and H)); Zone 3 – a zone where both advance- and retreat-phase tills are preserved, but with an intervening erosion surface (some of the advance-phase till has been removed, but erosion was insufficient to bite down into the preglacial surface (sites A and I)); Zone 4 – a zone of continuous till deposition and no erosion (this zone only occurs very close to the ice-sheet limit). More complex stratigraphies will result from oscillations of the ice margin and the migration of different basal thermal regimes (Boulton, 1996a,b).

Subglacial Landform–Sediment Associations

At the scale of continental ice sheets, we can identify ‘hard’ and ‘soft’ beds. Former hard beds existed in shield terrain, or ancient continental crust, where subglacial deposits tend to be thin and patchy and commonly streamlined at a wide

range of scales, forming flutings, megaflutings, megascale lineations, rock-cored drumlins, and leeside cavity fills. Bedrock surfaces covered in glacially eroded forms, ranging from microscale features (e.g., striae) to macro- and megascale forms (e.g., roches moutonnees and troughs) are common in such areas. Subglacially streamlined forms such as megaflutings and drumlins commonly record the last (deglacial) ice-flow directions, although earlier ice-flow directions may be recorded in some areas where older lineations were not obliterated by deglacial flow. Ribbed (Rogen) moraine (Dunlop and Clark, 2006) occurs almost exclusively in shield terrains and has been associated with one of three mechanisms: (1) local shearing and thickening of debris-rich basal ice (Bouchard, 1989), (2) partial modification of older streamlined forms following a shift in the ice-divide position (Boulton, 1987; Boulton and Clark, 1990), and (3) a subglacial sediment instability mechanism (Dunlop et al., 2008). Long esker networks are also common in areas of hard substrata, where they record late stages of drainage below ablating ice sheets (Aylsworth and Shilts, 1989; Shilts et al., 1987). Clark and Walder (1994) have argued that eskers are characteristic of hard-rock terrains because channelized, conduit flow is possible at the ice-bed interface. At a continental scale, eskers are more widespread on hard substrata, but they do occur on soft substrata, in some cases superimposed on drumlins and other bedforms. It is possible that on both hard and soft beds, subglacial drainage switched between channelized and distributed systems as ice thickness and gradient, and meltwater supply changed over the course of a glacial cycle.

Soft glacier substrata occur in areas underlain by weak sedimentary rocks or where accumulations of Quaternary sediments mask hard lithologies. Expansive sedimentary bedrock lowlands exist at the margins of the North American and Scandinavian shields (e.g., Kleman et al., 2008), which provided an outer zone of potentially deformable sediment below the great Pleistocene ice sheets. In such areas, the subglacial surface typically consists of fluted and drumlinized terrain underlain by varying thicknesses of subglacial sediments. Late-stage drainage events may be recorded by eskers and/or meltwater channels (Eyles, 1983b; Eyles and Eyles, 1992; Eyles and Menzies, 1983). In many areas occupied by Pleistocene ice sheets, subglacial sedimentary sequences may comprise tens of meters of vertically stacked tills and intervening stratified sediments (Figure 2). Till units may be laterally continuous for tens of kilometers, with remarkably uniform sedimentological characteristics and lithological composition (e.g., Boyce and Eyles, 2000). In many localities, stacked till units record flow interactions between ice lobes (e.g., Eyles et al., 1982; Hicock, 1992). Near the junction between two adjacent ice-flow units, changes in relative ice discharges can cause gradual or abrupt shifts in the ice-flow direction, as one flow unit becomes dominant over the other. As a result, debris from different source areas can be transported to the site, producing marked compositional stratification in which the lithological composition of till units varies systematically up-section. Such compositional changes are commonly paralleled by shifts in the preferred orientation of particle fabric modes, allowing sequences of ice-flow changes to be reconstructed in some detail (Berthelsen, 1978; Boston et al., 2010; Evans et al., 2008; Eyles et al., 1982). Vertical compositional changes can also occur in

Figure 2 A 30-m thick sequence of multiple tills on the Canadian prairies, Milk River, southern Alberta. Tills can be differentiated by color and bounding surfaces marked by clast pavements.

the absence of changes in flow direction. Boulton (1996b) has shown that till composition reflects the duration of glaciation, particularly the length of time available to transport debris from distant locations. Theory suggests that till composition should be dominated by local lithologies near the base and shift to predominantly far-traveled lithologies at the top, reflecting the passage of successive waves of debris from further and further upglacier.

Regional Distributions of Subglacial Landforms

Subglacial sediments and landforms exposed by glacier and ice-sheet recession commonly exhibit systematic spatial patterns, in which different types of landforms occur in distinct zones aligned parallel or transverse to former ice flow. Several factors influence the formation of subglacial sediments and landforms, including strength and hydraulic conductivity of the bed, basal thermal regime and the availability of meltwater, ice velocity, shear stress, and effective overburden pressure. Thus, landform zonation can be viewed as a mosaic produced in a variety of subenvironments beneath the parent ice sheet, either at a single moment in time or as a time-transgressive palimpsest resulting from ice advance or retreat (Kleman et al., 2006; Kleman and Glasser, 2007). Elongate, flow-parallel zones may mark the former position of flow units such as ice streams and marginal lobes, or meltwater drainage pathways, whereas transverse zones may record down-flow variations in basal conditions and their migration through time.

Ice-sheet advance over an area can be recorded by distinctive landform-sediment zones, particularly in regions underlain by weak rocks or unconsolidated sediments. For example, in the northern Great Plains of North America, arcuate belts of hummocky ice-thrust terrain and excavational basins commonly lie at the distal edges of drumlin fields. Some of the thrust belts have a subdued, streamlined appearance, and contain cupola hills and drumlins with low length/width ratios. The excavational basins and thrust ridges document glaciectonic disturbance near the ice margin, probably encouraged by cold-based conditions below the snout or surging (cf. Bluemle and Clayton, 1984; Clayton and Moran, 1974; Evans et al., 1999, 2008), and the streamlined terrain and drumlin belts record the subsequent advance of wet-based ice over the former marginal zone.

In regions where subglacial deformation was intense and prolonged, glactectonized thrust masses may be buried, their upper surfaces intensely sheared and incorporated within the subglacial deforming layer. The amount of subglacial modification commonly decreases down-ice, and landform assemblages exhibit a continuum from drumlins with high length/width ratios, through drumlins with low length/width ratios and cupola hills, to largely unmodified thrust masses. Such landform associations apparently represent progressively less effective or short-lived subglacial molding toward the ice limit. [Boyce and Eyles \(1991\)](#) attribute down-ice changes in drumlin morphometry and sedimentology in the Peterborough drumlin field south of the Dummer Moraine, Ontario, to variations in substratum characteristics and duration of glaciation. Specifically, they consider the down-ice variations in drumlin morphometry to be a function of decreasing duration of subglacial deformation toward the ice margin, with the northern part of the area having been stripped of its preexisting sediment because it was located beneath the ice-sheet interior (*cf.* [Boulton, 1996a](#)).

Cross-Cutting Lineations and Ice-Sheet Dynamics

Regional mapping of flow-parallel and transverse landforms can reveal large-scale patterns of ice-sheet flow and their

changes through time, yielding valuable information on ice-sheet evolution and dynamics. Reconstructed flow patterns for ice-sheet maxima demonstrate that ice sheets were not simple domes from which ice spread radially, but rather comprised multiple accumulation and dispersal centers ([Boulton et al., 1985](#); [Jansson et al., 2003](#); [Punkari, 1995](#); [Stokes et al., 2005](#)). Furthermore, it is possible to reconstruct the migration of ice divides and the switching of ice streams during a glacial cycle by mapping cross-cutting and superimposed subglacial bedforms (see [Kleman et al., 2006](#) for a review), assessing till fabrics and tracing indicator erratics. Analysis of Landsat satellite images and aerial photographs of glaciated terrains has enabled glacial geomorphologists to reconstruct changing ice-sheet flow directions, and numerous ice-flow landform assemblages have been identified, composed of drumlins, megafaultings, and megascale lineations, which are commonly superimposed on or cross-cut one another ([Figure 3](#)). [Clark \(1993\)](#) identified two relative age indicators that enable the sequence of ice flows to be reconstructed: (1) 'simple superimposition,' where one set of streamlined lineations is superimposed over another set with a different orientation, and (2) 'preexisting lineation deformation,' where deformation during a more recent ice-flow phase alters the form or continuity of preexisting lineations. According to Clark, the degree of

Figure 3 Flow sets comprising coherent assemblages of subglacially streamlined landforms (megalineations) produced during subsequent flow phases at the base of the former Laurentide Ice Sheet over Victoria Island, Arctic Canada. The flow sets record complex cross-cutting by ice streams that changed flow direction due to migrating ice divides. Reproduced from [Stokes CR, Clark CD, Darby DA, and Hodgson DA \(2005\)](#) Late Pleistocene ice export events into the Arctic Ocean from the M'Clure Strait ice stream, Canadian Arctic Archipelago. *Global and Planetary Change* 49: 139–162.

modification of earlier lineations forms a continuum, ranging from (1) a situation where there is no modification of the preexisting lineation to (2) a superimposition of smaller forms on the surface of older lineations to (3) a substantial breaching or deformation of the preexisting lineation and to (4) a total reorganization of sediment into a new orientation.

Ice-Sheet Marginal and Supraglacial Landform–Sediment Associations

At the margins of ice sheets and ice caps, supraglacially entrained debris is rare or absent and therefore debris for the construction of ice-marginal landforms must be derived from the glacier foreland or the bed, and elevated to higher levels by either proglacial or englacial glaciectonic processes, or pressurized meltwater flowing in englacial conduits. The processes and patterns of debris entrainment, elevation, and deposition at glacier margins are strongly influenced by glacier thermal regime and ice-margin activity, allowing some of the climatic and dynamic characteristics of former ice masses to be reconstructed from geological evidence.

Ice-sheet marginal and supraglacial landform–sediment associations can be differentiated on the basis of the nature of the glacier body responsible for their emplacement, particularly the dominant basal thermal regime. [Evans \(2009\)](#) and [Benn and Evans \(2010\)](#) use the concept of a thermal regime process–form continuum to help explain the spatial and temporal variability in landform–sediment associations produced at ice-sheet and glacier margins. At one end of the continuum are warm-based glacier termini, found in mid-latitude settings such as Iceland and southern Norway, where recessional dump and push moraines record margin oscillations on annual or longer timescales. At the other end of the spectrum are the termini of predominantly cold polythermal glaciers, where deformation and thickening of basal ice take place in the marginal cold-based zone, allowing accretion of thick sequences of debris-rich ice and the development of controlled moraine. In the middle of the process–form continuum lie moraines constructed in areas of discontinuous or sporadic permafrost, by glacier margins that can respond to decadal or seasonal climate forcings. Consequently, the typical range of landform–sediment associations can be reviewed under the three categories of active temperate, polythermal, and polar-continental margins.

Active Temperate Glacier Margins

Temperate glacier margins can be defined as those that are mainly wet-based, for at least part of the year, and generally occur in areas of discontinuous permafrost or in permafrost-free areas. A narrow frozen zone develops below the margin of many temperate glaciers during the winter, due to the penetration of a cold wave from the atmosphere through the thin ice at the edge of the glacier ([Kruger, 1994](#)). Additionally, small and discontinuous areas of net freezing can exist below some temperate margins in areas of discontinuous permafrost (e.g., [Lawson, 1979](#)), in some instances amounting to thick basal debris-rich ice sequences where supercooling takes place (e.g., [Alley et al., 1998](#); [Larson et al., 2010](#); [Lawson et al., 1998](#)).

Deposition at temperate glacier margins typically produces small dump moraines or push and squeeze moraines derived from sediment exposed on the glacier foreland. Modern examples have been described from Iceland, where thrusting mainly affects ice-contact fans built up against the ice front but can also relocate slabs of subglacial till ([Boulton, 1986](#); [Evans and Hiemstra, 2005](#); [Humlum, 1985](#); [Kruger, 1985, 1993, 1994](#)). Glaciers without extensive debris cover respond rapidly to seasonal temperature fluctuations, so glacier margins tend to oscillate on an annual basis even during recession, hence the term ‘active temperate.’ As a result, suites of recessional moraines are commonly formed during deglaciation except where glacier velocities are low and/or ablation continues throughout the year ([Boulton, 1986](#); [Kruger, 1994](#); [Sharp, 1984](#)). The areas between recessional moraines represent periods of rapid glacier retreat and commonly exhibit well-preserved subglacial landforms ([Evans and Twigg, 2002](#); [Evans et al., 2009](#); [Figure 4](#)).

Meltwater can have a profound influence on the landforms and sediments formed at temperate glacier snouts, and subglacial, ice-marginal, and supraglacial depositional assemblages are commonly substantially modified by proglacial glaciofluvial deposition and erosion during and following deglaciation. Landforms such as drumlins, eskers, and moraines may be heavily reworked by meltwater and/or buried by outwash sediments so that they are left as remnants or inliers within sandur plains ([Figure 4](#)). Even large ice-marginal moraines can be dissected or partially destroyed by meltstreams directly after emplacement ([Evans and Twigg, 2002](#); [Kruger, 1994](#); [Marren, 2002](#); [Price, 1969](#); [Thompson, 1988](#)). In some cases, virtually the entire depositional legacy of a temperate ice lobe takes the form of glaciofluvial sediments. Where subglacial and englacial drainage systems are well developed, sands and gravels can accumulate within conduits, and meltstreams emerging at the glacier surface can deposit considerable quantities of glaciofluvial sediment in supraglacial positions. Indeed, on some glaciers, glaciofluvial sediment constitutes the major part of the englacial and supraglacial sediment load close to the margins ([Gustavson and Boothroyd, 1987](#)). During deglaciation, uneven ablation of sediment-covered ice can lead to the development of ‘glacier karst’ ([Clayton, 1964](#)). Sediment deposited within conduits and in supraglacial outwash fans and lakes produces a complex assemblage of landforms including esker systems, kame ridges and plateaus, and pitted outwash. Distinctive spatial associations of glaciofluvial landforms deposited during ice wastage have been termed morphosequences ([Koteff and Pessl, 1981](#)). In such sequences, proglacial outwash passes up valley into kame and kettle topography, which is inset within ice-marginal kame terraces and moraines. Kame and kettle topography is locally refashioned into suites of river terraces by proglacial and postglacial streams.

Polythermal Glacier Margins

Polythermal margins are diverse in character as dictated by the extent of frozen and temperate ice at the bed, which in turn is controlled by the environmental conditions and glacier thickness. In essence, they are characterized by an outer cold-based zone and an upglacier wet-based zone. At present, such glacier margins are found mainly in areas of continuous permafrost. The thermal regime and geomorphic impact of glaciers in

Figure 4 Extract from a map of glacial landforms on the foreland of Breidamerkurjokull, Iceland. Tills are orange and their surfaces are fluted (green lines). The flutings are arranged in linear zones separated by push moraines (black line symbol). Overridden push moraines are colored red and eskers are denoted by arrow head symbols. Note that glaciofluvial outwash occupies corridors through the subglacial landforms and sediments, where meltwater excavated channels during deglaciation of the foreland. Reproduced from [Evans DJA and Twigg DR \(2002\)](#) The active temperate glacial landsystem: A model based on Breidamerkurjokull and Fjallsjokull, Iceland. *Quaternary Science Reviews* 21: 2143–2177.

permafrost regions is determined by ice thickness and activity ([Dyke, 1993](#)). Ice caps growing on thick permafrost must initially be entirely cold-based, but wet-based zones can develop in response to subglacial heating from geothermal heat and the strain heating produced by glacier flow. Thawing of the bed is most likely where glacier velocities are highest (e.g., in the vicinity of the glacier equilibrium line and in areas of flow convergence), and therefore, wet-based ice will be most extensive below glaciers with relatively high mass throughput and/or strong converging flow. In the upper parts of glacier accumulation areas, cold-based zones are likely to persist due to

low ice velocities and downward advection of cold firn. Cold-based ice occurs beneath the glacier margins where ice is thin, velocities are low, and proglacial permafrost extends below the glacier, and therefore, small low-activity glaciers in permafrost regions are likely to be cold-based throughout ([Etzelmueller and Hagen, 2005](#)).

The presence of wet-based ice up glacier from a frozen margin in polythermal glaciers has a profound impact on processes of debris entrainment, transport, and deposition. First, erosion below wet-based, sliding ice provides a source of debris which can be transported toward the margin in

Figure 5 Thrust-block moraine developed in raised marine sediments at the margin of the Eugenie Glacier, Dobbin Bay, Ellesmere Island, Arctic Canada. Note the marine shorelines notched into the front of the moraine attesting to higher sea levels during moraine construction.

regelation ice or a subglacial deforming layer. As this debris is transported into the frozen zone at the glacier margin, sequences of debris-rich basal ice develop as a result of net adfreezing (Hubbard, 1991; Weertman, 1961). These debris sequences are commonly thickened and elevated toward the glacier surface by strong compressive deformation resulting from ice deceleration at the frozen margin (Boulton, 1972; Etzelmuller et al., 1996; Goldthwait, 1951; Hambrey and Huddart, 1995; Knight, 1989; Tison et al., 1993), where bands of controlled moraine can be produced and later develop into ice-cored moraine arcs (Evans, 2009). Thick basal debris sequences also form where glaciers override buried ice dating from earlier glacial events (Evans, 1989b; Hooke, 1973). The long survival of buried ice in permafrost environments (e.g., Dyke and Evans, 2003) means that debris-rich ice may be recycled many times over several glacial cycles as glaciers advance and retreat. Common landforms at polythermal glacier snouts are composite ridges and thrust-block moraines, particularly in wide valley bottoms close to sea level where thick sequences of stratified sediment occur (Etzelmuller et al., 1996; Evans, 1989a,b, 1990; Evans and England, 1991; Hambrey and Huddart, 1995; Kalin, 1971; Figure 5). Where proglacial thrusting does not occur, glaciers commonly terminate in steep ice cliffs along which elevated basal debris is exposed, and frontal aprons, composed of dry calved ice blocks and fallen or in-washed debris, accumulate (Evans, 1989b). Following ice-margin retreat, belts of hummocky and controlled moraine are deposited upvalley from frontal aprons as a result of meltout and reworking of englacial debris. If the debris cover is thicker than the depth of summer melting (the active layer thickness), ice cores may survive indefinitely within frontal aprons and associated hummocky and controlled moraine (Evans, 2009). In cases where bedrock is close to the surface or glacier activity is low, moraines formed at the margins of polythermal glaciers may amount to no more than a line of boulders, attesting to a very low turnover of debris. Recessional moraines are uncommon and basal tills are rare or thin and patchy (Evans, 1990).

The amount of available debris reaches a minimum where polythermal glaciers are predominantly or entirely cold-based. Former glacier margins in such areas are most often marked by lateral meltwater channels cut into bedrock (Dyke, 1993;

Evans, 1990). These lateral channels form because surface meltwater is prevented from penetrating the glacier by low ice temperatures, so that it must drain over the surface and around the margin of the glacier. Where cold glacier tongues descend to the sea or ice-dammed lakes to form glacier ice shelves, they can deposit ice-shelf moraines (Dyke and Prest, 1987; England et al., 1978; Hodgson, 1994; Hodgson and Vincent, 1984; Sugden and Clapperton, 1981).

Polar-Continental Glacier Margins

Distinctive glacial landsystems are formed around the margins of glaciers in the polar deserts (Fitzsimons, 2003), for example, fringing parts of the Antarctic Ice Sheet, where the environment is cold, windy, and has a moisture deficit because sublimation exceeds precipitation. Local glaciers are entirely cold-based and are nearly free of debris, although some of the larger terrestrial outlet tongues of the Antarctic Ice Sheet are partly wet-based with cold-based margins and have stacked basal debris sequences similar to those of subpolar polythermal glaciers (Shaw, 1977a,b). Where thick basal ice sequences crop out, marginal aprons accumulate by gravitational processes, but with very limited reworking by meltwater. Within the marginal aprons, belts of hummocky and controlled moraines can develop from stacked and thrust englacial debris sequences. The topography of controlled moraines is inherited from englacial structures (Figure 6), such as debris bands and folds in debris-rich basal ice, and commonly forms ridges transverse to glacier flow (Shaw, 1977a,b). Entirely cold-based glaciers without stacked basal debris sequences leave very little imprint on the landscape, and end moraines commonly consist of little more than low ridges and, unlike subpolar glacier margins, marginal meltwater channels are rare. Thrust-block moraines occurring in front of some polar-continental glaciers (Fitzsimons, 1997) appear to require special conditions, because most of the proglacial sediment is deeply frozen and ice-cemented and has a high shear strength; it is likely that these moraines form by the proglacial thrusting of unfrozen lake-bottom sediments, because lake floors can remain unfrozen below a lake ice cover until glaciers advance into them.

Subaquatic Glacial Depositional Systems

Subaquatic depositional systems form a very important component of the ancient glacial geological record because (1) large parts of the Pleistocene ice sheets terminated in the sea or large proglacial lakes, depositing huge volumes of sediment in standing water; (2) subaquatic sediments tend to have high preservation potential and commonly preserve a more complete record of glaciation than terrestrial depositional systems; and (3) the study of subaquatic depositional systems yields important insights into the dynamics of former ice sheets, including the patterns of deglaciation, the location of the grounding lines of former ice streams, and episodes of rapid calving retreat and ice rafting as recorded in Heinrich Events.

Stratigraphic Architecture

The large-scale geometry or 'stratigraphic architecture' of subaquatic depositional systems is crucial to understanding environmental change in glacially influenced basins (e.g., Boulton,

Figure 6 Schematic diagram showing the origin of ice-cored (controlled) moraine ridges at the margin of a polar glacier. Reproduced from Powell RD (2003) Subaqueous landsystems: Fjords. In: Evans DJA (ed.) *Glacial Landsystems*, pp. 313–347. London: Arnold, with permission.

1990; Eyles and Eyles, 1992; Hambrey, 1994). A large body of information is available on subaqueous depositional systems for hundreds of formerly glaciated sites, and many depositional models have been proposed (e.g., Ashley, 1995; Eyles et al., 1985; Fyfe, 1990; Gravenor et al., 1984; Molnia, 1983; Powell and Domack, 1995; Figure 7). It has become clear that, although the lateral and vertical relationships between sediment–landform associations such as morainal banks, grounding-line wedges, and distal drapes are very varied, they reflect the interaction of relatively few groups of variables. The most important are (1) the topography and tectonic setting of the basin; (2) the extent, configuration, and dynamics of glacier and floating ice and the position of associated depocenters; and (3) changes in water depth due to eustatic and isostatic

cycles and the life cycle of proglacial lakes (Boulton, 1990; Eyles and Eyles, 1992; Martini and Brookfield, 1995; Powell, 1984, 1990; Powell and Domack, 1995). Subaqueous depositional systems can be classified according to their position of formation relative to the ice front. Powell (1984) defined four zones as subglacial, ice proximal, ice shelf, and ice distal. The subglacial zone lies behind the glacier-grounding line and is reviewed above. Facies deposited in this zone form downglacier-thickening sheets of basal till and associated lenses of water-sorted material. The ice-proximal zone encompasses subaqueous environments adjacent to the glacier-grounding line. The thickness of sediment packages deposited in the ice-proximal zone is related to the glacier snout retreat rate; slow retreat or quasi-stable conditions will encourage the

accumulation of large volumes of sediment, whereas during rapid calving retreat, a large proportion of debris will be rafted away, restricting the amount of ice-proximal deposition.

Sediment associations include push and thrust moraines, grounding-line fans, morainal banks, deltas, DeGeer moraines, and grounding-line fans. Sediment gravity flows are common in the ice-proximal zone due to high sedimentation rates, ice push, iceberg calving, storm waves, tidally induced pressures below ice shelves, and morainal bank collapse. Subaqueous outwash and sediment flows both commonly form prograding beds dipping away from the glacier margin, known as clinoforms. The upper parts of such clinoforms may be erosionally truncated during glacier advance, forming a subhorizontal erosion surface overlain by basal till. The ice-shelf zone occurs in polar climates where ice below the pressure-melting point floats and produces glacier and sea-ice ice shelves. Deposition in this zone is dominated by undermelt and rainout, forming drapes of dropstone diamicton and mud. The ice-distal zone is dominated by ice-rafted debris and muds formed by the settling of suspended mineral grains and microfaunal remains. Rainout, current reworking, and gravitational resedimentation produce sequences of massive and stratified sediment tens to hundreds of meters thick and spanning several glacial cycles. The long-term preservation potential of such sequences is high, and they are well represented in the ancient geological record (Eyles, 1993).

Fjords

Glacial stratigraphic architecture in fjords is strongly influenced by topography. Overdeepened basins act as sediment sinks, whereas bedrock sills provide pinning points where ice-proximal depositional systems can accumulate. Additionally, the presence of steep flanking slopes encourages gravitational reworking of sediment and debris input from ice-free terrain. The sedimentary infill of fjord basins can be usefully divided into three broad units deposited during glacier advance, maximum, and retreat. The advance stage of a glacial cycle is typically represented by a basal till unit or an erosion surface. Till thickness generally increases down fjord toward the glacier limit, reflecting erosion, and downglacier transport of pre-existing sediment and bedrock fragments (Boulton, 1990). Beyond the glacier limit, extensive blankets of mud and diamicton may record distal glacimarine deposition during the advance phase, but they are typically buried by younger glacimarine sediments. Sediments relating to glacial maximum conditions are commonly located at pinning points where reduced calving rates encourage ice-margin stability (Greene, 1992; Warren and Hulton, 1990).

Typical sediment–landform associations include push or thrust moraines, grounding-line fans, morainal banks, and deltas (Powell, 2003). In low-relief fjord basins, lateral moraines may be preserved on the valley sides, but in high-relief settings, such moraines are generally rapidly destroyed by paraglacial reworking after glacier retreat. Lateral moraines with exceptionally low gradients indicate the former extent of floating ice shelves. Beyond the ice limit, blanket-like drapes of fine-grained sediments and diamictic muds record suspension sedimentation from turbid overflows and dumping from icebergs (Powell and Molnia, 1989). During glacier

retreat, depositional zones migrate upfjord, and progressively more distal facies are laid down on top of older units. Pauses in glacier retreat may be marked by push or thrust moraines, grounding-line fans, or morainal banks (Boulton, 1986). Substantial ice-marginal accumulations such as large morainal banks and deltas tend to be associated with topographic pinning points. Glacimarine sediments and landforms in fjords may be raised above sea level by isostatic uplift following deglaciation. The emergence of ice-proximal associations above sea level provides a readily accessible source of information on former ice margins in regions where terrestrial ice-marginal accumulations are commonly not well preserved.

Continental Shelves

The glaciation of shelf areas may arise through the advance of terrestrial margins in a seaward direction, the thickening and grounding of sea ice encouraged by lower sea level, or a combination of these processes. The impact of glaciation on a continental shelf may be direct, where the shelf has hosted a grounded glacier mass, or indirect, where it merely received distal glacimarine sediments during a glacial cycle. Patterns of sedimentation are dependent on a number of interrelated factors, including the extent and configuration of glacier ice, basin history and tectonic setting, bathymetry, oceanography, glacial thermal regime, and sediment supply (e.g., Eyles, 1993; Powell, 1984). Powell (1984) considered the influence of ice-margin configuration and thermal regime on patterns of sedimentation on continental shelves and identified various glacimarine regimes on the basis of the nature of the ice source (valley glacier or ice sheet), glacier thermal regime, and glacier front characteristics (tidewater cliff or ice shelf). Tectonic setting also exerts a strong influence on the style and preservation of glaciogenic sediments on continental shelves (Eyles, 1993; Hambrey, 1994) and includes passive margins, convergent margins, and rift basins (e.g., Eyles et al., 1991; Powell and Domack, 1995; Vorren, 2003).

Large Proglacial Lakes and Epicontinental Seas

During deglaciation of the Pleistocene ice sheets, ice margins were commonly in contact with large water bodies, either proglacial lakes ponded between the ice and topographic barriers, or arms of the sea that flooded isostatically depressed and glacially overdeepened parts of continental interiors (Teller, 2003). The extent and evolution of many of these water bodies has been reconstructed from the sedimentary record, in combination with shoreline evidence, pollen and microfaunal records, and dating programs (e.g., Eronen, 1983; Teller, 1995). These large proglacial water bodies encouraged rapid ice-margin retreat by calving and may have triggered some episodes of ice advance or surges by encouraging low effective pressures below the glacier margin (Fyfe, 1990; Stokes and Clark, 2003). Depositional systems in such settings are similar to those of continental shelves (Figure 7), although there are some important differences. First, fresh lake water and brackish shallow marine conditions reduce the importance of suspended-sediment transport in overflows and interflows, so that underflow deposits are better represented in ice-proximal and distal systems. Second, the seasonal alternation between

deposition by underflows in summer and settling of clay particles in winter produces annual varves in lakes. Third, proglacial water bodies are prone to sudden changes in water level, due to the opening and closing of outlets by glacier margin fluctuations and periodic jokulhlaups and recharge events. The resulting cyclic water-level changes can be recorded by discrete sediment packages bounded above and below by erosion surfaces, and can add considerable complexity to stratigraphic sequences (Brookfield and Martini, 1999; Martini and Brookfield, 1995). Fourth, proglacial lakes and epicontinental seas can receive substantial amounts of sediment from recently deglaciated land surfaces surrounding the basin as well as from the glacier margin (Martini and Brookfield, 1995).

Sediment–Landform Associations of Mountain Glaciation and Glaciated Valleys

The glacial landforms and sediments of mountain environments have been synthesized for a variety of physiographic and latitudinal zones ever since the concept of a glaciated valley landsystem was introduced by Boulton and Eyles (1979) and Eyles (1983c). A variety of depositional settings has been elucidated by Benn et al. (2003) in a model that incorporates the controls of debris supply on landform development. A plateau icefield landsystem has been proposed by Rea et al. (1998) and Rea and Evans (2003) based upon observations on Norwegian and Icelandic ice caps. Glaciated valleys are unique in that they are influenced by valley-side debris inputs and the topographic confinement of depositional basins. The influence of these factors varies from valley to valley, and it is useful to subdivide glaciated valley landsystems into low-relief and high-relief types. Low-relief settings include valleys in ancient mountain belts where the vertical distance between valley floor and summit ridges is generally <1000 m (e.g., the glaciated valleys of Scotland, Norway, and Labrador). High-relief settings are characterized by extensive steep valley sides rising thousands of meters above the valley floor. Such environments are commonly associated with young or tectonically active fold mountains such as the European and New Zealand Alps, the High Andes, and the Himalayas, where relative relief may be 3000 m or more. Features common to both low- and high-relief mountainous terrains are ice-dammed lakes and paraglacially reworked materials.

Low-Relief Mountain Environments

Valley glaciers in low-relief mountain terrain carry relatively small amounts of supraglacial debris, so subglacial landforms commonly escape burial during deglaciation and may be very well exposed at the surface (Figure 8). The upper limits of glacier occupancy in glaciated valleys can be preserved as erosional ‘tidemarks,’ or trimlines, on valley sides. In recently deglaciated terrain, trimlines are often marked by differences in vegetation cover on either side of the former glacier limit, whereas in older glacial landscapes, periglacial trimlines may be preserved where frost-shattered terrain on upper slopes gives way abruptly to ice-scoured bedrock on lower ground (Ballantyne and McCarroll, 1995; Thorp, 1981, 1986). The margins of valley glaciers in low-relief mountain areas are

Figure 8 A landsystem model for deposition by valley glaciers with relatively low supraglacial debris concentrations. 1, Supraglacially entrained debris; 2, periglacial trimline; 3, medial moraine; 4, fluted till; 5, paraglacial reworking; 6 and 7, lateral moraine displaying within-valley asymmetry. Reproduced with permission from Benn DI and Evans DJA (1998) *Glaciers and Glaciation*. London: Arnold.

commonly delimited by lateral–frontal dump and push moraines (Benn and Lukas, 2006). Moraine characteristics are strongly influenced by catchment lithology, and in valleys underlain by resistant, crystalline rocks, lateral moraines may be little more than ridges of boulders. In contrast, thrust moraines may occur where glaciers come into contact with thick, unconsolidated sediments such as glacial marine clays and silts. Meltwater deposition at some glacier margins is recorded by ice-marginal ramps and fans (e.g., Lukas, 2005). Lateral moraines may be much larger on one valley side than the other, a phenomenon known as ‘within-valley asymmetry’ due to one or a combination of four factors: (1) the differential extent of extensive, debris-supplying rock walls, (2) glacier pushing of preexisting materials that are unevenly spread over the foreland, (3) cross-valley differences in lithology or structure, and (4) differences in glacier dynamics on either side of a valley (Benn, 1989; Bennett and Boulton, 1993; Evans, 1999; Matthews and Petch, 1982).

The combined use of lateral moraines and other ice-marginal landforms and trimlines allows the dimensions of former valley glaciers and their equilibrium-line altitudes (paleo-ELAs) to be reconstructed with considerable accuracy, yielding important input for glaciological models or paleoclimatic studies (Ballantyne, 1989; Nesje and Dahl, 2000; Thorp, 1991). Glacier retreat in low-relief mountain environments may be recorded by recessional moraines and/or linear hummocky moraine superimposed on subglacial sediments and landforms. The size and spacing of such moraines reflect the availability of debris and the frequency and duration of still stands or readvances of the margin (Benn, 1992; Benn and Lukas, 2006; Bennett and Boulton, 1993; Eyles, 1979). Assemblages of chaotic hummocky moraine may occur in pockets

Figure 9 Lateral moraines and ice-contact fans deposited at the margin of a debris-charged valley glacier in the Lahul Himalaya, India.

within fields of recessional moraines, possibly due to the isolation and stagnation of sediment-covered ice remnants (Benn, 1992). Large areas of hummocky moraine can be produced by incremental marginal stagnation, whereby chaotic moraines are deposited in a 10–500 m wide marginal zone of debris-mantled ice which retreats upvalley during deglaciation (Eyles, 1983a,c). Assemblages indicative of more general stagnation, such as chaotic hummocky moraine inset within ‘staircases’ of subhorizontal kame terraces, occur on some flat-lying valley floors (Benn, 1992).

High-Relief Mountain Environments

On account of their high sediment yields, high-relief mountain environments contain valley floors that are commonly filled by very large volumes of sediment, particularly in tectonically active ranges such as the Southern Alps of New Zealand, the Himalayas, and the Andes (Clapperton, 1993; Kirkbride, 1995; Owen and Derbyshire, 1989, 1993). Valley glaciers in such settings typically have extensive covers of supraglacial debris, and sedimentation around glacier margins forms large lateral-frontal dump moraines and ice-contact fans and ramps (Figure 9; Benn et al., 2003; Boulton and Eyles, 1979; Evans et al., 2010; Hambrey et al., 2008; Humlum, 1978; Owen and Derbyshire, 1989, 1993; Shulmeister et al., 2009; Small, 1983).

Debris-mantled glaciers (Nakawo et al., 2000) have relatively muted responses to climatic change, because large lateral-frontal moraines limit the amount of glacier advance, and extensive supraglacial debris cover inhibits ablation of the underlying ice. Therefore, unlike their low-relief counterparts, valley glaciers in high-relief terrain tend not to deposit numerous dump and push moraines but instead remain at the limits imposed by lateral-frontal moraines until advance or retreat is triggered by significant climatic change; so, the landform record of a retreating debris-mantled glacier consists of major moraine complexes, representing periods of stability, separated by extensive tracts of hummocky moraine deposited during episodes of ice-margin wastage and stagnation. The vast latero-frontal moraine complexes produced during ice wastage commonly form dams for proglacial and supraglacial lakes, giving rise to periodic glacial lake outburst floods when dams are breached by lake water (Cenderelli and Wohl, 2003; Clague and Evans, 1994). The thick supraglacial and ice-marginal sediments of valley glaciers in high-relief terrain largely mask subglacial landforms and sediment so that the former beds of such glaciers are rarely preserved in the geomorphological record.

Moraine Forms and Genesis

D J A Evans, Durham University, Durham, UK

Introduction

Moraines can be generally described as accumulations of sediment/debris on the surface or at the margins of an ice sheet or glacier. They can be constructed at either terrestrial or subaqueous ice margins where internal structures and sedimentary characteristics reflect the processes involved in their emplacement. A range of large-scale morainic features constructed by glaciotectonic processes are excluded from this article because they are classified as glaciotectonic landforms and therefore described elsewhere. This separation of morainic forms is based upon the definitions proposed by Benn and Evans (2010), specifying that moraines are those in which glaciotectonized sediments or bedrock constitute >25% of the unit area of the moraine. Terrestrial moraines include push and squeeze moraines, dump moraines and ice-marginal aprons, and latero-frontal moraines and fans and ramps. Supraglacial debris accumulations form medial moraines and hummocky/controlled moraine. Subaqueous depocenters include morainal banks, coalescent subaqueous fans, and De Geer moraines, and the interface between subaqueous and terrestrial environments can be marked by ice-shelf moraines.

Push and Squeeze Moraines

Push moraines are small moraine ridges, usually <10 m in height, produced by minor (often annual) glacier advances in either subaqueous or terrestrial settings (e.g., Evans and Twigg 2002; Sharp, 1984; Figure 1). Other terms include washboard moraines, cross-valley moraines, and corrugated ground moraines. Although the term 'push moraine' has been employed in the past to refer to large-scale glaciotectonized moraine ridges, more specific terms are now available for such features and so they are not included here. Push moraines vary widely in composition and can consist of subglacial till, mass-movement deposits, water-sorted sediments, or large boulders, depending on the nature of the sediment on the glacier foreland. Where glacier margins are debris covered, push moraines can consist mainly of supraglacial material dumped onto the foreland during the summer and pushed up during winter. Push moraines commonly have asymmetric cross-profiles, with gentle proximal slopes, often covered with small flutings and steep distal slopes. Push moraines are broadly arcuate in planform, but in detail are often irregular and winding, reflecting the morphology of the glacier snout. For example, where the glacier snout is indented by radial crevasses, push moraines have sawtooth planforms, with downvalley-pointing teeth and upvalley-pointing notches (Evans and Twigg, 2002; Evans et al., 2009; Matthews et al., 1979; Price, 1970; Sharp, 1984; Figure 2). It is common to find younger moraines overlying, or completely consuming, parts of older moraines wherever summer retreat is small and/or some winter readvances are more substantial than usual

(Boulton, 1986; Evans and Twigg, 2002; Sharp, 1984). Where glacier snouts are quasistable or have reached a position where they are in equilibrium with their environment, large terminal moraines may accumulate by annual accretion. Similarly, the absence of moraines relating to individual years within a field of annual moraines can be explained by unusually large winter advances or longer-term readvances. These can result in ice advance that exceeds several years of annual retreat and so winter push moraines can be destroyed or incorporated into a larger moraine ridge (Boulton, 1986; Krüger, 1993, 1994). The construction of larger push moraine ridges has been explained in some settings as the result of stacking of till slabs due to submarginal freeze-on of subglacial sediment and its release by melt-out over a seasonal cycle (Evans and Hiemstra, 2005; Krüger, 1996; Matthews et al., 1995; Figure 3). The formation of minor moraine ridges by squeezing of saturated sediment from beneath ice margins has been observed in front of several glaciers whose snouts are predominantly underlain by poorly drained, fine-grained till (Price, 1970; Figure 4). Additionally, subaqueous squeeze moraines have been described by Andrews and Smithson (1966). Newly formed squeeze moraines have steep or vertical sides and are rarely more than 1 m high. Squeeze moraines tend to degrade rapidly and are commonly subject to reworking by ice push; therefore, unmodified squeeze moraines are probably rare in the geomorphological record.

Dump Moraines and Ice-Marginal Aprons

Material accumulating at the surface of a glacier through the melt-out of debris-rich folia is ultimately subject to remobilization by mass flowage, fall, or fluvial transport. Where such material exists at the glacier margin, its remobilization may result in it being dumped onto the adjacent terrain during ice recession. Depending on the rate of debris accumulation and glacier activity, a variety of sediment-landform associations will be created. For retreating glaciers, dumping of supraglacial material onto the former subglacial surface slowly emerging from beneath the ice produces a thin veneer of coarse-grained diamicton or perhaps only sporadic collections of boulders (Eyles, 1979). Dump moraines form where the ice margin remains stationary during debris accumulation (Boulton and Eyles, 1979), although they will be bulldozed into push moraines if the glacier undergoes a subsequent readvance. Dump moraine size is related to supraglacial debris volume and the length of the stillstand period. Small dump moraines will form where glaciers remain stationary during the winter but retreat during the summer, each moraine marking one winter's increment of debris accumulation. The largest and most spectacular dump moraines, however, form at the margins of debris-mantled valley glaciers which occupy similar positions for considerable periods (Figure 5). The dumping of large quantities of supraglacial debris around glacier margins builds up

Figure 1 Contemporary push moraines being constructed at the margin of Flajokull, Iceland.

Figure 2 Aerial photograph of the margin of Fjallsjokull, Iceland in 1965, showing a sequence of annual push moraines with 'saw-tooth' planforms (© University of Glasgow and Landmaelingar Islands).

latero-frontal dump moraines (Boulton and Eyles, 1979; Small, 1983, 1987) through the processes of sliding, rolling, flowage, and fall from the ice surface to produce ice-contact scree. In mountain environments, the debris may be predominantly passively transported rockfall material, consisting of coarse, angular clasts with little matrix. However, actively transported debris can also crop out near valley glacier margins due to the elevation of basal debris septa (linear debris concentrations in glacier ice), thereby introducing matrix-rich debris to some dump moraines. On some latero-frontal moraines, there is a tendency for clast roundness to increase in a down-moraine/down-valley direction due to the increasing proportion of actively transported debris in the moraines closer to the former glacier centerline (Benn and Ballantyne, 1994; Evans, 1999; Matthews and Petch, 1982).

Where dump moraines are deposited on steep valley sides, debris derived directly from the glacier is interdigitated with sediment from the valley walls, producing an internal stratigraphy composed of (i) stratified debris flows and fall sorted

debris avalanche material with beds dipping away from glacier margin, (ii) subhorizontally bedded alluvium deposited as kame terraces along the ice margin, and (iii) debris flows and fall sorted screes from valley-side paraglacial fans. Removal of lateral support by glacier recession results in mass failure of the inner slopes of the moraines. In many cases, such failures clearly extend up into the screes which were deposited against the lateral moraines. During glacier thinning, dump moraines are abandoned and their inner faces are subject to collapse and reworking (Figure 6). A new inset dump moraine may be formed within the older one if the glacier restabilizes at a new position, but such moraines will be unstable if they are deposited on top of dead ice masses. Alternatively, renewed thickening of the glacier may dump material on top of the old dump moraine, which may become completely buried. In this case, periods of nondeposition may be recorded by paleosols or even buried trees, which are valuable sources of paleoclimatic data in Alpine environments (Röthlisberger et al., 1980). Localized breaching of latero-frontal moraine loops by advancing glacier snouts can give rise to the development of breach-lobe moraines (Deline, 1999).

Distinctive dump moraines known as frontal- or ice-marginal aprons form around the margins of some Arctic and polar glaciers (Evans, 1989; Fitzsimons, 1997; Shaw, 1977). These moraines form where debris and ice blocks accumulate at the base of steep, terminal ice cliffs by a combination of dry calving and limited melting (Figure 7). When forming, the aprons have steep ice-contact slopes and gentler ice-distal slopes determined by the properties of the debris. However, they will be subject to considerable modification following deglaciation due to the ablation of incorporated ice blocks.

Latero-Frontal Fans and Ramps

Deposition by debris flows and glaciofluvial processes around stationary glacier margins can result in the construction of latero-frontal fans and ramps, consisting of coalescent debris fans, which descend from the glacier snout (Benn et al., 2003; Owen and Derbyshire, 1989, 1993; Figure 8). After glacier recession, such landforms are identifiable by their pronounced asymmetric cross-profile, comprising a distal slope that is much shallower in gradient than on latero-frontal dump moraines and a steep proximal or ice-contact face. Fans deposited predominantly by glaciofluvial processes grade distally into outwash tracts or sandar, producing 'outwash head' landforms (Benn et al., 2003; Kirkbride, 2000; Krzyszkowski, 2002; Krzyszkowski and Zielinski, 2002). In some situations where moraines are absent, fans and ramps provide the only evidence of former ice-marginal positions. Ice-contact fan morphology develops over a considerable period, sometimes involving several generations of deposition with intervening periods of abandonment. During fan accumulation, active depocenters shift position, reflecting changes in the morphology of the ice margin and fan surface. As the fan progrades, surface angles tend to become progressively reduced. Meltwater exiting from englacial (within the ice) positions or draining the glacier surface locally excavates the ice-contact fan/ramp faces to produce inset meltwater fans. In active mountain belts, ice-contact fans can reach heights of hundreds of meters, attesting to very

high rates of debris transfer (Evans et al., 2010). Because debris flow fans and ramps are deposited partly over glacier ice, they may be characterized by pitted or degraded surfaces after ice melt-out. When ice-contact fans are abandoned by glacier retreat, the inner faces are susceptible to collapse and may

provide material for lateral moraine development during ice recession.

The sedimentology of latero-frontal fans/ramps is dominated by massive, often bouldery debris flow diamictos with beds up to tens of meters thick, interbedded with water-sorted

Figure 3 A model of push moraine formation by the incremental stacking of till slabs during an annual cycle of subglacial deformation, freeze-on, and melt-out. Reproduced from Evans DJA and Hiemstra JF (2005) Till deposition by glacier sub-marginal, incremental thickening. *Earth Surface Processes and Landforms* 30: 1633–1662. (1) Situation in late summer at typical Icelandic glacier snout where subglacial processes include lodgement and sliding (A), bedrock and sediment plucking (B), subglacial deformation (C), and ice-keel ploughing (D) in a temporally and spatially evolving process mosaic. (2) During early winter, the thin part of the glacier snout freezes onto part of the subglacial till. The till slab that freezes onto the ice sole is likely to be from the more porous A horizon (A). (3) The later winter readvance initiates failure along a decollement plane within the A horizon or at the junction with the more compact B horizon, resulting in the carriage of A horizon till onto the proximal side of the previous year's push moraine. (4) In the early summer, the melt-out of the till slab (A) initiates porewater migration, water escape, and sediment flow (small arrows) and sediment extrusion due to glaciostatic and glaciodynamic stresses. (5) The late summer situation is again followed by winter freeze-on and marginal stacking of subglacial till produced by the reworking of existing subglacial sediments and fresh materials advected to submarginal locations from up-ice. Repeated reworking of the thin end of submarginal till wedges produces overprinted strain signatures and clast pavements.

Figure 5 Latero-frontal moraines at the margin of the Hooker Glacier, New Zealand, formed by the accumulation of debris dumped at the highly debris-charged ice margin when it stood at its Little Ice Age limit. Some glacier pushing will also have contributed to moraine construction.

sediments and dipping away from the glacier snout (Evans et al., 2010; Krzyszkowski and Zielinski, 2002; Lukas, 2005). These sequences comprise coalescent ice-marginal fans. Pockets of glaciolacustrine sediment, which have in some instances been glaciotectionized, attest to the occurrence of short-lived proglacial lakes ponded between the ice margin and the fans during ice retreat phases.

Medial Moraines

Medial moraines are prominent features on the surfaces of many glaciers and are the surface expression of a medial debris septum, which may be a shallow feature or extend to the base of the glacier (Figure 9). Ablation results in the concentration of the debris septum on the glacier surface. Medial moraines on existing glaciers have been classified by Eyles and Rogerson (1978) based on the relationship between debris supply and morphological development. Three broad types were recognized, including (i) ablation-dominant moraines, which emerge at the surface as the result of the melt-out of englacial debris; (ii) ice stream interaction moraines, which find

Figure 6 A model of lateral moraine formation by ice-marginal dumping of debris. Reproduced from Small RJ (1983) Lateral moraines of Glacier De Tsidjore Nouve: Form, development and implications. *Journal of Glaciology* 29: 250–259.

immediate surface expression downstream from glacier confluences, often by the merging of two supraglacial lateral moraines; and (iii) avalanche-type moraines, which are transient features formed by exceptional rockfall events onto a glacier surface. Medial moraines do not have good preservation potential because they contain relatively little debris and are subject to intense reworking during glacier melt. They sometimes can be traced from modern glacier surfaces onto proglacial surfaces, where they may be recognizable as diffuse spreads of debris with distinctive lithological composition or particle morphologies (Evans and Twigg, 2002). However, such moraines commonly have no marked surface expression and may

Figure 7 Ice-marginal apron produced by dumping of debris and dry calving of ice blocks from a subpolar glacier snout, Ellesmere Island, Arctic Canada.

Figure 8 Debris flow-dominated ice-marginal fans marking the former margin of the Batal Glacier in the Lahul Himalaya.

be very difficult to recognize once the glacier foreland becomes vegetated. Recognition of ancient medial moraines is easier where they consist of large boulders, which may be traced back to their source outcrops (e.g., Dawson, 1979).

In certain situations, ice stream interaction-type medial moraines have a high preservation potential and may

Figure 9 Medial moraines at the margin of Breidamerkurjökull, Iceland. The recession of the glacier snout has resulted in the lowering of the medial moraines on to subglacial landforms to produce a thin rubbly veneer visible in the foreground.

constitute interlobate moraines. For example, on the west coast of New Zealand, very large ice stream interaction medial moraines, which are greater than 100 m high in some areas, have been produced by the coalescence of ancient piedmont glaciers with well-developed lateral moraines. Because these features accumulated essentially as lateral moraines, they contain sediments characteristic of ice-marginal deposition, but the moraine cores commonly display glaciotectionic structures, and in places, carapaces of subglacial till record glacier coalescence and overriding. Benn and Evans (2010) have suggested that wherever such interlobate features become overridden by glacier ice, they may evolve into megaflutings.

Some medial/interlobate moraines may comprise large quantities of glaciofluvial sediment, for example, where lobate margins of an ice sheet coalesce. Two large examples occur at the southern margins of the former Laurentide Ice Sheet. The Harricana Interlobate Moraine, formerly separating the Hudson Bay and Labrador sectors of the receding ice sheet, stretches for 1000 km southward from James Bay to Lake Simcoe, Ontario, Canada (Veillette, 1986, 1988) and comprises a series of ridges up to 10 km wide and 100 m high. The Burntwood-Knife Interlobate Moraine, formerly separating the Hudson Bay and Keewatin sectors of the receding Laurentide Ice Sheet, covers a distance in excess of 500 km on the west side of Hudson Bay and is composed of broad ridges of glaciofluvial sediment and till. Individual segments are up to 12 km long, 4 km wide, and 60 m high (Dredge et al., 1986; Dyke and Dredge, 1989; Klassen, 1986). The large quantities of sands and gravels comprising these moraines were deposited in proglacial lacustrine environments during the final stages of the Laurentide Ice Sheet, attesting to the large-scale reworking of medial moraine debris during glacier recession. Glaciofluvial reworking of medial moraine debris during ice wastage can produce features indicative of former medial moraine locations even though they are strictly different landforms. For example, continuous esker systems may demarcate the former positions of medial moraines in glaciers or ice sheets where debris septum ensures constant sediment supply to englacial drainage networks (e.g., eskers and medial moraines in Breidamerkurjökull, Iceland; Evans and Twigg, 2002; Price,

1969, 1973). Similarly, a low-relief kame and kettle topography centered on the bottom of the Athabasca Valley near Jasper in Alberta, Canada is interpreted as a former supraglacial medial moraine by Levson and Rutter (1989; Figure 10).

Figure 10 A model of medial moraine formation based on Canadian Rocky Mountain case studies (Levson and Rutter, 1989). Gradual lowering of the medial moraine results in the formation of a linear ice-cored moraine. This develops into a chain of kettle lakes and hummocky terrain comprising rubby supraglacial debris.

Hummocky Moraine and Controlled Moraine

The term 'hummocky moraine' has been employed in a wide range of senses. As a purely descriptive term, it has been applied to moundy, irregular morainic topography exhibiting varying degrees of order, ranging from entirely chaotic assemblages of mounds to suites of nested transverse ridges (Attig and Clayton, 1993; Benn, 1992; Bennett and Boulton, 1993; Sissons, 1967; Figure 11). Genetically, it has been used to encompass landforms with a variety of origins, including deposition in association with active and stagnant ice, and deformation (e.g., Aario, 1977; Bennett and Boulton, 1993; Eyles et al., 1999; Gravenor and Kupsch, 1959; Hoppe, 1952). The term 'hummocky moraine' is now used in a more restrictive sense (Benn and Evans, 2010) to refer to moraines deposited during the melt-out of debris-mantled glaciers (e.g., Hoppe, 1952, 1959; Sharp, 1949, 1985). This genetic definition should only be applied to suites of moraines whose origin has been established by detailed mapping and sedimentological analyses, because generalized descriptions of surface morphology alone are insufficient to determine moraine genesis. For example, many tracts of so-called hummocky moraine in the Highlands of Scotland, originally believed to be chaotic ice-stagnation topography (Sissons, 1967), have subsequently been recognized as nested push and dump moraines, or drumlins draped by supraglacial and ice-marginal deposits (Benn, 1992; Bennett and Boulton, 1993). Hummocky moraine deposited from debris-mantled ice can appear chaotic or linear in pattern, depending on the distribution of debris in the parent glacier and the patterns of debris redistribution and reworking during ice wastage. Occurrences with pronounced transverse linear elements are termed controlled moraines (Evans, 2009). Hummocky moraine is the end product of topographic inversion cycles during the ablation of debris-mantled ice (Figure 12). During ice ablation, debris is transferred away from topographic highs on the glacier surface by mass movements and meltwater, exposing ice cores to renewed melting and creating new depressions in former high points. Further debris reworking and topographic development is achieved by meltwater streams meandering between dirt cones, the collapse of englacial tunnels, and the enlargement of supraglacial lake basins. Several cycles of

Figure 11 Hummocky moraine produced by the melting of a debris-charged surge snout, Tungnaarjökull, Iceland.

debris reworking and topographic inversion may occur before the debris is finally deposited in a series of irregular mounds and ridges.

The distribution of controlled moraines is inherited from debris concentrations or septa within the parent glacier (Evans, 2009). Transverse debris concentrations close to glacier margins may result from the thrusting of debris along shear planes (Bishop, 1957; Goldthwait, 1951; Souchez, 1967), the emergence of basal debris frozen onto the glacier sole (Boulton, 1970; Swift et al., 2006), or reworked

ice-marginal aprons (Evans, 1989; Hooke, 1970; Hudleston, 1976; Shaw, 1977). Such transverse septa control the pattern of differential ablation on the glacier surface, producing linear ice-cored ridges which eventually become separated from the snout to form ice-cored moraines (Dyke and Evans, 2003; Evans, 2009, 2010, 2011; Østrem, 1964). The morphological expression of englacial structures is always most striking while the moraines retain ice cores (Figure 13). However, uneven sediment redistribution during ice-core wastage means that the final deposits tend to consist of discontinuous transverse ridges with intervening hummocks, preserving only a weak impression of the former englacial structure. Reworking by supraglacial meltwater systems also acts to destroy large tracts of controlled moraine before they can be deposited on the ground surface. Patterns of debris reworking and deposition can also be controlled by crevasses or other lines of weakness within the ice, which can guide the final stages of glacier disintegration (Gravenor and Kupsch, 1959).

The sedimentology of hummocky moraine is complex, reflecting multiple cycles of redeposition during its formation (Kjær and Krüger, 2001). Typical facies associations consist of interbedded debris flows and other mass-movement deposits, laminated lacustrine sediments, and glaciofluvial sands and gravels, in varying degrees of disturbance (Eyles, 1979; Paul, 1983). The constituent debris may be actively or passively transported, depending on the position of the moraine relative to debris transport paths in the parent glacier. In some cases, debris from different sources and transport paths may remain segregated within the moraine, giving rise to compositional stratification (Benn, 1992).

Figure 14 A reconstruction of the depositional environment in which morainal banks accumulate at the glacier grounding line, based on the example at Achnasheen, Scotland (from [Benn, 1996](#)). (1) Subglacial till, (2) mass flows, (3) mass flow diamictons, (4) subglacial meltwater portal, (5) subaqueous outwash, (6) laminated sediments, and (7) iceberg dump mound.

Morainal Banks and Coalescent Subaqueous Fans

Wherever glacier grounding lines remain quasistable for long periods of time and/or sediment fluxes to the glacier margin are high, subaqueous moraines will form by the accumulation of sediment along the glacier margin. Debris may be delivered from the ice surface, the melt-out of debris-rich ice and icebergs, the release of unfrozen till from a subglacial deforming layer, or reworking of older deposits ([Figure 14](#)). This debris can be reworked in conveyor belt fashion by erosion off the subglacial face and deposition on the subaqueous slope ([Powell, 1984](#)).

Subaqueous moraines that extend up into shallow water can also be exposed to wave energy, leading to winnowed and sorted gravels and sands in their upper parts ([Powell, 1984](#)). Some subaqueous moraines mainly consist of coalescent grounding-line fans, deposited at the same time at the efflux points (exit locations) of adjacent meltwater conduits. For example, the Salpausselka Moraines of Finland consist of transverse chains of ice-contact fans and deltas deposited during stillstands of the southern margins of the Scandinavian ice sheet where it contacted deep water ([Fyfe, 1990](#)). Similarly, some large-scale moraines, comprising partially glaciotectionized grounding-line fans, occur in eastern Maine, USA ([Ashley et al., 1991](#)) where they are arranged laterally along former grounding-line positions and are associated with tunnel mouth and esker deposits. A similar depositional scenario is envisaged by [Sharpe et al. \(2007\)](#) for the Oak Ridges Moraine in Ontario, Canada.

Some subaqueous moraines are formed mainly by dumping and other gravitational processes at the foot of terminal ice cliffs. This is especially the case where subpolar glaciers with thick basal debris sequences contact the sea, releasing large amounts of debris in environments where there is only limited subglacial meltwater ([Powell, 1984](#)). At many glacier margins, however, gravitational deposits are interbedded with subaqueous outwash, particularly at the margins of temperate glaciers where meltwater is abundant. For example, [McCabe et al. \(1984, 1987\)](#), [McCabe \(1985, 1986\)](#), and [Eyles and](#)

Figure 15 Aerial photograph of De Geer moraines in Quebec, Canada (National Aerial Photograph Library A14882-91).

[McCabe \(1989\)](#) present Pleistocene examples of interbedded gravitational and outwash deposits from the east central coast of Ireland in which channelized subaqueous outwash and debris flow facies interdigitate with ice-rafted dropstone muds. These sediments show evidence of glaciotectionic deformation and underlie arcuate belts of hummocky topography.

De Geer Moraines

Named after Swedish geologist Gerard De Geer, De Geer moraines commonly occur in fields of closely spaced ridges in association with subaqueous sediments and mark the intermittent retreat of water-terminating glaciers ([Figure 15](#)). Many models have been proposed to account for De Geer moraine formation, but the consensus is that they mark former ice-margin positions, where sediment is deposited or pushed up during brief stillstands or minor readvances. In common with terrestrial push moraines, De Geer moraines are characterized

by steeper distal than proximal slopes, lobate forms with acute interlobe angles pointing up glacier, and truncated sections due to partial overriding by later moraines (Boulton, 1986). The formation of subaqueous moraines with steep ice-distal slopes and gentle ice-proximal slopes has also been linked to the calving of floating glacier snouts, perhaps on a yearly basis (Aartolahti, 1972; Holdsworth, 1973). In contrast, De Geer moraines may result from the squeezing of saturated sediment out from beneath the ice margin (Andrews and Smithson, 1966).

The notion that several De Geer moraines may be produced simultaneously has been proposed by Hoppe (1957), Lundqvist (1989), and Zilliacus (1989). This implies formation in basal crevasses a short distance behind glacier margins in a similar fashion to terrestrial crevasse fills (cf. Solheim, 1986), and indeed De Geer moraines are often juxtaposed with probable crevasse-squeeze ridges (cf. Ottesen and Dowdeswell, 2006; Ottesen et al., 2008; Todd et al., 2007). Specifically, transverse crevasses are formed in areas of extending flow and then widened during partial flotation of the ice margin. Moraines are thought to form when the water level drops and the glacier is lowered onto the substratum, which is squeezed up into the basal crevasses. Tabular icebergs would later break off along the transverse crevasses, thus ensuring that the moraines were not later overridden by the glacier. Such an explanation actually implies a crevasse-squeeze origin for the ridges and suggests that the glacier snouts responsible for their construction underwent draw-down and fracturing (Lundqvist, 1989) possibly in response to surging (Zilliacus, 1989). Such an origin would make the ridges directly comparable with terrestrial crevasse-fill ridges on surging glacier forelands (Evans and Rea, 1999, 2003; Sharp, 1985).

Similarly, features referred to as 'lift-off moraines' have been identified in seismostratigraphic investigations of the

Scotian and mid-Norwegian shelves by King and Fader (1986) and King et al. (1991). The production of lift-off moraines is thought to be related to fracture patterns in the base of a retreating glacier snout, involving a genesis similar to that proposed by Lundqvist (1989). It is uncertain whether lift-off moraines are produced individually by single events or simultaneously as groups (King et al., 1991).

Ice-Shelf Moraines

Ice-shelf moraines are formed where debris is deposited or relocated around the margins of ice shelves or floating glacier tongues. The crestlines of such moraines tend to be horizontal or have very low gradients, reflecting the low gradient of ice shelves that have zero or very low basal shear stresses. The gradients of ancient ice-shelf moraines, however, may be steeper due to postglacial isostatic tilting, so their gradients should be corrected with reference to the sea-level record. The recent ice-shelf moraine at the margin of the George VI Sound ice shelf, Antarctica, formed where complex ice pressure ridges were induced by flow against Alexander Island. A horizontal moraine ridge consequently formed over a distance of 120 km along the promontories of Alexander Island where basal debris was brought to the glacier surface by ablation and thrusting (Figure 16). Sediments within the moraine include subglacial debris entrained on Alexander Island and the Antarctic Peninsula, glaciofluvial and lacustrine sediments from ice-marginal streams and ponds, and marine sediments and fauna derived from freezing on at the grounding line on Alexander Island (Sugden and Clapperton, 1981). Similarly, Glasser et al. (2006) report inset moraines of single- or multiple-crested ridges containing a variety of material, including ice cores, constructed on Bratina Island by the McMurdo Ice Shelf.

Figure 16 A model for the development of the George VI Sound ice-shelf moraine, Antarctica. Reproduced from Sugden DE and Clapperton CM (1981) An ice-shelf moraine, George VI Sound, Antarctica. *Annals of Glaciology* 2: 135–141.

They propose that ice-shelf moraine production involves the entrainment of debris by anchor ice formation over offshore shoals, which is then mixed with medial moraine debris on the ice-shelf surface as it pushes onshore. Ancient ice-shelf moraines are rare (e.g., England et al., 1978; Evans et al., 2002), but a spectacular example occurs at the former north-western margin of the Laurentide Ice Sheet in Viscount Melville Sound, where extensive linear belts of till (Winter Harbour Till), between the altitudes of 60 and 150 m above present sea level, blanket the shores of Byam Martin, Melville, Banks, and Victoria islands and extend eastward to north Baffin Island (Dyke et al., 1992; England et al., 2009; Hodgson and Vincent, 1984; Klassen, 1993).

Quaternary Vulcanism: Subglacial Landforms

J L Smellie, University of Leicester, Leicester, UK

© 2013 Elsevier B.V. All rights reserved.

Glossary

Caprock: Subhorizontal layer of resistant rock (e.g., lava) that overlies (caps) less-resistant rocks (usually fragmental material).

Cryolithosphere: Permanently frozen subsurface broadly corresponding to the permafrost zone, where any water present occurs as ice; mainly used in studies of Mars.

Effusive: Said of a volcanic eruption characterized by the relatively nonexplosive ejection of flowing molten lava.

Felsic: Relating to lava (magma) compositions that are often pale colored and are relatively rich in silica and poor in iron and magnesium, such as andesite, dacite, trachyte, phonolite, and rhyolite.

Glaciovolcanic: All types of volcano interactions with ice in all its forms (including snow and firn) and, by implication, any meltwater derived from that ice by volcanic heating.

Lava-fed delta: A distinctive flat-topped volcanic landform that is the volcanic equivalent of a sedimentary delta and formed where lava enters a lake or the sea. It comprises subhorizontal subaerial lava overlying steep-dipping glassy breccias. The presence of lava-fed deltas is what gives mafic tuyas their distinctive morphology.

Mafic: Relating to lava (magma) compositions that are dark colored and are relatively rich in iron and magnesium and poor in silica, such as basalt and basaltic andesite.

Monogenetic: Formed during a single, usually relatively short-lived event (e.g., an eruption).

Morphometry: The measurement and mathematical analysis of landforms and other objects.

Polygenetic: Formed during more than one event (e.g., multiple eruptions).

Stratovolcano: A stratified volcano composed of alternating lava and fragmental rocks (e.g., tephra), commonly long-lived, large and constructed during multiple eruptions (i.e., polygenetic).

Tephra: Volcanic ash and other solidified or molten rock explosively ejected during an eruption.

Tindar: Conical or ridge-like pile dominantly composed of volcanic ash generated by explosive subaqueous eruptions in a glacial environment (meltwater-filled vault or lake) as a result of subglacial eruptions. Some authors restrict the name to ridge-like outcrops only.

Tuff cone: Conical pile with a summit crater, formed of explosively erupted volcanic ash (tephra).

Tuya: Flat-topped steep-sided volcanic landform, the product of volcanic eruptions through a glacier or ice sheet, in the sea or a nonglacial lake. The word is most commonly used for an edifice constructed as a result of subglacial eruptions, particularly those involving mafic magmas with lava-fed deltas, but is sometimes applied to flat-topped volcanic constructs erupted in other environments and involving magmas with more evolved (felsic) compositions.

Volcano–ice interactions are common on Earth (e.g., [Edwards et al., 2009b](#); [Smellie and Chapman, 2002](#), and papers therein). A few eruptions have been observed and there are many extinct edifices of Quaternary age and older. Where ice sheets have shrunk or long since vanished, the subglacial volcanic edifices are frequently highly accessible and permit close-up, detailed field analysis. They are overwhelmingly the products of basaltic eruptions since basaltic volcanism is the dominant mode of volcanic activity on Earth. Edifices formed by more evolved magmas also occur but are much less common and most examples occur in Iceland ([McGarvie, 2009](#)). The internal structure, hydraulic evolution, and eruptive processes have been relatively well investigated (e.g., [Edwards et al., 2009a](#); [Gudmundsson et al., 2004](#); [Schopka et al., 2006](#); [Skilling, 2009](#); [Smellie, 2000, 2001, 2006, 2008](#); [Smellie and Hole, 1997](#); [Smellie and Skilling, 1994](#); [Smellie et al., 1993, 2011a](#); [Stevenson et al., 2009, 2011](#); [Tuffen et al., 2002a,b, 2009](#)). Most of those studies concentrated on documenting the lithofacies present, which were extremely poorly known prior to the 1990s, and using the sequence architecture to reconstruct the mode(s) of edifice construction and associated eruption dynamics. By contrast, the study of subglacial volcanic landforms has not advanced

far and there are very few publications ([Hickson, 2000](#); [Komatsu et al., 2007](#); [Smellie, 2007, 2009](#)).

Subglacial eruptions are now called glaciovolcanic. The term ‘glaciovolcanic’ refers to all types of volcano interactions with ice in all its forms (including snow and firn) and, by implication, any meltwater derived from that ice by volcanic heating ([Smellie, 2006](#)). It includes not only eruptions and their products that took place underneath a glacier or ice sheet (i.e., subglacial), but also subaerial volcanic products (e.g., lavas, pyroclastic flows, etc.) that simply ponded and chilled against an ice barrier or else interacted with snow by overriding or entrainment ([Harder and Russell, 2007](#); [Lescinsky and Sisson, 1998](#); [Mee et al., 2006](#); [Thouret, 1990](#)). The many different types of glaciovolcanic sequences identified so far can be used to obtain a uniquely wide range of critical parameters of past terrestrial ice sheets, for which other (i.e., nonvolcanic) records are typically patchily and poorly preserved and rely on geomorphologic criteria that are highly susceptible to reworking (e.g., moraines, trimlines). They are thus a valuable, but still under-used, proxy for documenting paleoenvironmental changes over time (e.g., [Edwards and Russell, 2002](#); [McGarvie et al., 2006, 2007](#); [Mee et al., 2006](#);

Smellie, 2000; Smellie and Skilling, 1994; Smellie et al., 2006b, 2008, 2009, 2011b; Stevenson et al., 2006). Reliably identifying and documenting the occurrence of subglacially erupted volcanoes and their distribution over geological time is also central to understanding the inventory and dynamic behavior of past and present water on Earth.

Terrestrial landforms also provide our best empirical basis for interpreting remotely observed features on Earth's nearest planetary neighbors (i.e., the Moon, Mars, and Venus) and understanding their geological evolution. Mars, like Earth, also has a substantial inventory of volatile elements, including an unusually thick cryolithosphere (i.e., subsurface ice) and surface ice in the form of small polar ice caps that may have been much more extensive in times past. It is also dominated by basaltic volcanism. At present, the description, quantification, and interpretation of Mars volcanic landforms are wholly reliant on satellite observations and comparisons with possible terrestrial analogs. The Mars landforms include candidate examples of mafic tuyas (volcanic table mountains; see later) and tephra cones and ridges, which have been erupted subglacially (e.g., Chapman, 2003; Chapman and Tanaka, 2001; Head and Pratt, 2001; Ghatan and Head, 2002; Chapman and Smellie, 2007; Martínez-Alonso et al., 2011). Their identification was used to suggest the former existence of a much-expanded south polar ice cap in Hesperian times (~1.8–3.5 Gy) and formerly extensive mid- to low-latitude ice during past high-obliquity periods. However, definitive evidence for glaciovolcanism on Mars remains elusive.

This article focuses on volcanic landforms that were erupted and constructed subglacially. There are no known distinctive landforms that were constructed following volcanic interactions with snow or subsurface ice; subaerial volcanic constructs that simply chilled against surface ice are also excluded (e.g., Harder and Russell, 2007; Lescinsky and Fink, 2000; Lescinsky and Sisson, 1998; Mee et al., 2006; Stevenson et al., 2006). The ability to make robust identifications of volcanic landforms, and understanding the intrinsic and extrinsic environmental controls on their formation, are important research frontiers that are set to become increasingly important for deciphering ancient planetary glacial records (Smellie et al., 2008, 2009, 2011a,b).

Subglacial Volcanic Landforms

Subglacial eruptions on Earth have formed several different types of volcanic landforms (Hickson, 2000; Smellie, 2009). However, our knowledge of these landforms is currently so poor that their classification and description are almost certainly oversimplified. The descriptions that follow also take little account of post eruptive erosional effects, which can be significant especially for glaciovolcanic edifices containing weak piles of waterlogged volcanoclastics that are easily glacially modified and can also undergo multiple postglacial sector collapses once the buttressing effect of the surrounding ice is removed (e.g., Komatsu et al., 2007; Tuffen et al., 2002b). However, they are described here essentially as pristine primary morphologies. The different volcanic landforms reflect differences in (1) lithofacies and sequence architecture; (2) intrinsic properties of the enclosing ice sheet or glacier (i.e., thickness,

thermal regime, and meltwater hydraulics); and (3) magmatic composition, volatile content, rheology, and discharge (Hickson, 2000; Smellie, 2000, 2001, 2009; Tuffen et al., 2002a). All but two of the landforms identified so far are volcano edifices. The two exceptions (called subglacial sheet-like sequences) are also common subglacial volcanic products and they form an additional, although poorly defined, volcanic landform resulting from subglacial eruptions. The several volcanic landform types are illustrated in Figure 1 and summarized in Table 1. The glaciovolcanic data used in this study are presented in Table 2.

Practically all of the published examples of subglacial volcanic landforms were constructed during relatively short-lived monogenetic eruptions beneath temperate or wet-based ice. There are no descriptions of monogenetic edifices formed under cold-based ice, although some of the products of those eruptions have been described (Smellie et al., 2011a). There are also very few descriptions of long-lived (i.e., millions of years) subglacial polygenetic stratovolcanoes or shield volcanoes and there are indications that the compound morphometry of those larger landforms may be very different from those formed by monogenetic eruptions (Edwards and Russell, 2002; Smellie et al., 2008, 2011a). Overall, our fundamental knowledge of subglacial volcanic landforms is at an early stage, and the following descriptions are heavily biased toward the monogenetic examples and should be viewed in that context.

This article is based mainly on reviews by Smellie (2007, 2009). The landforms are divided empirically into mafic examples, typically basalt to basaltic andesite or andesite in composition, and felsic types, principally dacite and more evolved magmas. There is a clear hierarchy of landform types (Figure 2). However, the distinction is unlikely to be so clear-cut in nature and some felsic subglacial volcanoes, particularly those with intermediate compositions, will probably be found that show features more commonly found in mafic systems, and vice versa. A preliminary assessment of the landform morphometry is included in each section, using volume and aspect ratio as empirical parameters. Aspect ratio is defined as the ratio of maximum height (above volcano base) to edifice width. For sheet-like sequences, deposit thickness is used rather than height since the coeval edifice dimensions are either unknown or undiagnostic. Aspect ratio is an admittedly crude empirical parameter and it does not closely reproduce many true volcano profiles, but it is still a useful and informative parameter that can enable distinctions to be made. It cannot resolve the distinctive combination of relatively flat tops and steep perimeter cliffs that characterize mafic tuyas, and it also fails to recognize summit craters. However, this is not always a problem. For example, craters are among the first casualties of post eruptive erosion, particularly when constructed of poorly consolidated tephra.

Mafic Tuyas

Mafic tuyas are the most distinctive and frequently described subglacial volcanic edifices. They are also known nongenetically as table mountains or mesas, although not all table mountains and mesas are tuyas. Tuyas are also the commonest

Figure 1 Approximately true-scale vertical profile sketches showing the principal characteristics of the major subglacial volcanic landforms described in this article. Sheet-like sequences are not shown but would resemble pillow sheets in dimensions.

subglacial volcanic landform to have been identified on Mars. The edifices are typically small and steep-sided, with relatively flat or, more typically, gently domed summit regions with or without a crater, and oval to straight-sided plan shapes (van Bemmelen and Rutten, 1955; Jones, 1969; Figure 3). Although commonly regarded as products of monogenetic eruptions, even some volumetrically quite small examples can be polygenetic (Jones, 1969; Skilling, 2009; Smellie, 2001; Werner and Schmincke, 1999; Wörner and Viereck, 1987; Figure 3(c)). Published examples of much larger polygenetic mafic tuya-type volcanoes are scarce, possibly because the edifices would need to be erupted consistently beneath an ice cover that persisted or repeatedly reformed during the lifetime of the volcano (millions of years). The Mount Haddington volcano, on James Ross Island, Antarctica, is a large polygenetic terrestrial example formed from repeated large-volume (typically tens of cubic kilometers) pahoehoe lava-fed deltas (Smellie et al., 2008). It rises 1.6 km, has a basal diameter of 60 km, encircling cliffs up to 600 m high and was constructed in multiple extrusive phases since the latest Miocene (Figure 4(a)). It has a low surface profile similar to a shield volcano but has the steep margins characteristic of confinement by ice. However, those margins are not primary but are a result of modification by numerous arcuate collapses accentuated by subsequent glacierization. Other examples are common in northern Victoria Land, also in Antarctica. They are mainly late Miocene in age (~10–5 Ma) and are shield volcanoes largely constructed from multiple relatively thin aa lava-fed deltas (Smellie et al., 2011a; Figure 4(b)). Aa lava-fed deltas are different in their lithofacies and emplacement characteristics from pahoehoe deltas. Of potential importance here is the

observation that the subaqueously deposited foreset section in each aa delta (formed of massive or poorly bedded lobe-hyaloclastite) typically dips at a lower angle than equivalent hyaloclastite breccia foresets in pahoehoe lava-fed deltas, so the conspicuous steep margins characteristic of pahoehoe deltas are much less pronounced (Smellie et al., 2011a). The volcanoes individually rise to ~2 km and are typically ca. 20–30 km in diameter. Like Mt Haddington, morphologically the Victoria Land edifices seem to simply resemble nonglacial mafic shields and only the lithofacies provide unambiguous evidence for a glacial regime. Because they do not form a distinctive tuya-like landform, neither they nor Mt Haddington are tuyas, despite their construction from multiple superimposed lava-fed deltas.

Monogenetic mafic tuyas are defined by the presence of lava-fed deltas, which give tuyas their distinctive ‘flat’ top. Thus, they require a meltwater lake to form in and, if a lava-fed delta is absent, the landform is unlikely to be a mafic tuya (Figure 5). The deltas represent a late subaerial progradational phase of edifice-building by relatively rapid lateral extension (Skilling, 2002; Smellie, 2000, 2001, 2006) and they have a distinctive sequence architecture comprising a relatively thin caprock (topsets) formed of flat-lying subaerial lava overlying steep-dipping, homoclinal, glassy volcanic breccias (foresets) formed by the mechanical disintegration of the caprock lava during quenching where it reached and entered water, in this case a glacial lake (Figure 5). Two types are known: pahoehoe and aa deltas (cf. Skilling, 2002; Smellie, 2006; Smellie et al., 2011a). They have different lithofacies due to the different emplacement dynamics of the feeding lavas. Described aa lava-fed deltas have less steep delta fronts (typically $\leq 10^\circ$), than pahoehoe deltas (~25–35°). However, only

Modified from Smellie JL (2009) Terrestrial sub-ice volcanism: Landform morphology, sequence characteristics and environmental influences, and implications for candidate Mars examples. In Chapman MG and Keszthely L (eds.) *Preservation of Random Mega-Scale Events on Mars and Earth: Influence on Geologic History*, vol. 453, pp. 55–76. Geological Society of America Special Papers.

thin-ice-emplaced aa deltas have been described (Smellie et al., 2011a) and aa deltas emplaced in much thicker ice might have steep flanks comparable with pahoehoe deltas. No monogenetic tuyas constructed from aa lava eruptions have yet been described, whereas descriptions of pahoehoe-fed tuyas are common (e.g., Jones, 1969; Skilling, 2009; Smellie, 2006). Although tuyas commence construction as a subaqueous tuff cone and/or pillow mound (see later), those earlier-formed constructs do not significantly affect the final shape of the edifice. The flat or gently convex top is a subaerial volcanic shield constructed after the ice sheet was melted through completely during the eruption and it is formed of lavas with a summit crater or small pyroclastic cone of scoria or agglutinate. The principal limitation on the lateral extent of a mafic tuya is the volume of magma discharged over time, since deltas will advance as long as space is available and magma is supplied. By contrast, tuyas formed by eruptions within wet-based glaciers might be limited to heights less than 750–1000 m, since meltwater formed during eruptions in much thicker ice sheets should always theoretically float the surrounding glacier, and a stable meltwater lake (necessary for a lava-fed delta to form) will not occur (Smellie, 2009). A height limitation does

not apply to tuyas erupted in cold-based ice since that ice is frozen to its bed and cannot be lifted hydraulically. Although these suggestions are speculative, model based and not yet supported by observed eruptions, it might be significant that the largest wet-ice-emplaced monogenetic mafic tuyas in the present dataset (much expanded from Smellie, 2009) are 900–1000 m high, that is, the theoretical limit although it might simply reflect the rarity of mafic eruptions sufficiently sustained or voluminous to penetrate ice 1 km thick (see also Smellie, 2009, for further explanation and discussion).

Area is plotted against volume in Figure 6. Mafic tuyas have the largest volumes of any subglacial volcanic landform and their areas are also among the largest. They define a moderately well-defined trend with the highest volume:area ratio (mean 0.43) for any of the subglacial volcanic landforms (Figure 6(b)). The trend is curved (concave-up) and fits a power law or polynomial distribution very well (Figure 6(a)). Figure 7(a) shows aspect ratios using, as the horizontal dimension, the basal length of edifices defined as the *maximum* horizontal extent. The length is strongly affected by the mode of eruption: whether from fissures or point sources. Fissure length is a tectonically controlled variable and is not an intrinsic

Data are for monogenetic volcanoes only.

Heights are edifice heights, i.e. above surrounding pre-volcanic basement. They are likely maxima.

Tuya surfaces, in particular, may be several tens of meters lower.

Less reliable data (mainly from topographical maps) shown in italics.

Figure 2 Hierarchy of subglacial volcanic landforms. The dashed arrows indicate possible evolutionary trends between landforms that are commonly related in a single edifice (within dashed-line boxes). With the possible exception of mafic tuyas, each landform can exist without a different precursor landform and some probably always exist in isolation (e.g., felsic domes/lobes).

volcano-determined dimension. The division into discrete fields for each of the different types of volcano morphologies described in this paper, identified by Smellie (2007) using a smaller dataset, are generally not evident in the larger dataset now available. Tuya landforms in subfield 'a' (Figure 7(a)) reflect central-vent (i.e., point source) eruptions and are relatively symmetrical outcrops, while those in subfield 'b' are elongate fissure-erupted tuyas. Intuitively, central-vent eruptions on a sloping bedrock surface might also lead to asymmetry in the resulting tuya as the deltas will flow preferentially downhill and distort the edifice (cf. Smellie et al., 2011b, Figure 4).

In Figure 7(b), aspect ratio is plotted against width, defined as the *minimum* horizontal extent. Because the selected widths are perpendicular to fissure length, they reflect volcano construction processes rather than tectonics. The diagram illustrates that there might be a difference in aspect ratio between mafic and felsic subglacial landforms, with most mafic centers, of any morphological type, characterized by lower ratios ($< \sim 0.23$). There is significant overlap in values, however, although some overlap is probably due to post-eruptive erosional effects modifying the pristine landforms and changing their aspect ratios (especially likely for Russian mafic tuyas and tuff cones; see Komatsu et al., 2007). A subordinate subfield of much wider mafic tuyas is also present in Figure 7(b) (subfield 'b'). The simplest explanation for subfield 'b' in Figure 7(b) is that those edifices were constructed during unusually voluminous

Figure 3 Examples of mafic tuyas. (a) Herdubreid (Iceland) viewed looking north. It rises about 800 m and is probably the best-known mafic tuya. (b) Three large mafic tuyas in Iceland (Thorisjökull, Geitlansjökull, and Eiriksjökull, from left to right) exhumed by the postglacial retreat of the Langjökull ice cap. Thorisjökull tuya is about 600 m high and 10 km wide. The approximately coincident summit elevations suggest that they erupted through the same ice sheet and thus might be of similar age. (c) Hlödufell, a mafic tuya 1200 m high in Iceland. This tuya shows two flat-lying summit surfaces indicating that the edifice was constructed in stages and might be polygenetic (see Skilling, 2009). Note the strong morphological contrast with the narrow ridge (Jahrhettur; a tindar) with multiple peaks, formed of subglacially erupted mafic tephra, seen emerging from the Langjökull icefield in the right background.

eruptions, when the associated lava-fed deltas prograded laterally to a greater extent than tuyas in subfield 'a'. If true, both subfields in Figure 7(b) should in reality be continuous. The separation may be an artifact of the currently available data set, which is still relatively small, and the two fields will probably merge as more data become available.

As stated before, the largest monogenetic mafic tuyas measured so far are 900–1000 m in height, recording eruptions through contemporaneous ice sheets of comparable thickness and those heights are within the range of maximum heights (750–1000 m) predicted for tuyas erupted in wet-based ice.

Figure 4 Examples of large subglacially erupted polygenetic volcanoes. (a) Synthetic view of James Ross Island (Antarctica) viewed looking northwest. This is the world's largest-known subglacially erupted basalt shield volcano, about 60 km in diameter and 1.6 km high. It is constructed from multiple superimposed lava-fed deltas that are exposed in tall encircling cliffs. The cliffs formed by major sector collapses and subsequent glacial scouring. ASTER image draped on a DEM. Approximately three times vertical exaggeration. (b) Satellite view of Coulman Island, northern Victoria Land, Antarctica. The volcano margins are now cliffs several hundred meters high formed probably mainly by extensive marine erosion. Although a glaciovolcanic edifice, like Mt Haddington, it resembles other, nonglacial shield volcanoes and a glaciovolcanic origin for both volcanoes can be deduced only from a study of the lithofacies (Smellie et al., 2008, 2011a).

By contrast, the James Ross Island and northern Victoria Land subglacial polygenetic shield volcanoes are considerably taller (1.5–2 km), indicating that the theoretical height limit on mafic tuyas does not apply to polygenetic centers. This is because of the ability of an ice cover to reform on a stratovolcano soon after the cessation of each eruptive phase. Thus each effusive eruption on a shield (or strato-) volcano records the

thickness of the coeval ice draping the volcano, and it may always be much less than 750–1000 m even though the volcano grows to a greater height. This was the case on James Ross Island (1.6 km summit), where the ice sheet never exceeded 850 m (and was typically much less) and it was ≤ 300 m thick on the late Miocene northern Victoria Land polygenetic shields, each of which were constructed to summit elevations of 2000 m (Smellie et al., 2008, 2009, 2011b).

Felsic Tuyas

Some subglacial flat-topped, steep-sided volcanic landforms with felsic compositions have been described as tuyas (Kelman et al., 2002; McGarvie, 2009; Tuffen et al., 2002b). Compared to mafic tuyas, very few felsic examples have been described. Their compositions include andesite, dacite, and rhyolite. Apart from a trachyte example observed by the author on Ross Island, Antarctica, and rare examples with tephriphonolite and mugearite compositions in northern Victoria Land (also Antarctica; Smellie et al., 2011a), it appears that felsic magmas generally do not form lava-fed deltas (necessary for a mafic tuya, above). The internal structure of felsic tuyas is also very different from that of mafic tuyas although they share common characteristics of a flat-lying caprock of subaerial lava overlying subaqueous lithofacies (water-erupted/deposited tephra or water (or ice)-chilled lava; e.g., Tuffen et al., 2002b, Figure 3; Smellie, 2009; Stevenson et al., 2011).

At least two types of felsic tuyas are identified based on their internal structure: (1) tephra-dominated and (2) lava flow dominated. In tephra-dominated felsic tuyas, the flat cap is formed of horizontal or gently dipping, relatively thin (typically a few tens of meters) subaerially emplaced felsic lavas, which overlie a much thicker pile (few hundred meters) of fine-grained tephra (Figure 8). The tephra core is usually obscured by lava scree and is therefore poorly exposed (Stevenson et al., 2011; Tuffen et al., 2002b). By contrast, the lava flow dominated felsic tuyas are distinctive flat-topped columns or short blade-like ridges, also flat-topped. They are formed almost entirely of subhorizontal ice-impounded subaerial felsic lavas (Figure 9), although some of the lavas may also be plastered onto the subvertical tuya flanks (Mathews, 1951). Andesite-dacite lava-dominated systems have mainly been described so far, and fragmental deposits are typically absent or scarce (Kelman et al., 2002; Mathews, 1951). Like mafic tuyas, the lava caprock in both types of felsic tuyas formed after the ice sheet had melted through completely, apart from a unique rhyolitic example described by McGarvie et al. (2007) at Prestahnukur, Iceland, in which the edifice may have developed without the coeval ice carapace being melted through. Moreover, it has a less well-developed flat caprock than occurs in undoubtedly subaerial felsic tuyas. These characteristics are more similar to exogenous subglacial felsic domes (see below). However, other features such as the presence of a 300-m-thick basal pedestal of volcanoclastics (perlitized lobe-bearing breccias rather than tephra) and a much higher volume:area ratio than felsic domes, are possibly more akin to felsic tuyas. The Prestahnukur example illustrates that some glaciovolcanic outcrops can be hard to classify within the range of morphometric types currently recognized.

Figure 5 Cartoon of a monogenetic mafic tuya forming in a wet-based ice sheet, illustrating the internal organization of the principal lithofacies that construct the tuya and possible main meltwater discharge routes. The thickness of the overlying permeable layer is exaggerated, for clarity.

There are few data for felsic tuyas so it is difficult to be didactic about their morphometry. The data hint that all felsic tuyas may share similar (high) volume:area ratios to the mafic tuyas (Figure 6(b)). In Figure 7, it is clear that felsic tuyas have slightly to markedly higher aspect ratios than mafic tuyas, and are comparable with those for subglacial felsic domes. Together, they have among the highest aspect ratios of most subglacial volcanic landforms measured so far.

Pillow Mounds, Ridges, and Sheets

Subglacial pillow mounds, ridges, and sheets are formed mainly of pillow lava and less common hyaloclastite breccia. All described examples are basaltic in composition, but there is no intrinsic reason why more andesitic and even dacitic magmas should not form pillows (e.g., Stevenson et al., 2009) although the different rheologies of the more evolved magmas may affect the final edifice dimensions and, therefore, morphometry. Many of these landforms occur in the cores of basaltic tuyas and are therefore largely obscured from view, where pillow lava effusion is usually regarded as a ubiquitous early stage of tuya construction (e.g., Jones, 1969; Smellie and Hole, 1997; Werner and Schmincke, 1999). The landforms include (i) relatively low oblate mounds with moderately dipping sides and smooth profiles in examples erupted from central vents; (ii) subdued ridges with gentle slopes that were erupted from fissures; and (iii) extensive thin sheets (Figures 10 and 11). Examples include the subglacial pillow mounds in British Columbia examined by Dixon et al. (2002), which are formed solely of pillow lava extruded under ice sheets that may have been >2 km thick, and pillow-lava centers draped unconformably by agglutinate at Seal Nunataks, Antarctica, which formed within an ice sheet >600 m thick (Smellie and Hole, 1997). By contrast, pillow sheets are only a few tens of meters thick, yet may extend laterally 10 km or more (Snorrason and Vilmundardóttir, 2000, and unpublished). Pillow sheets are currently only known from Iceland and have not yet been described in detail. Their formation, their internal

structure, and even whether they are dominantly formed of pillow lava, are unclear at present.

Because they have not been studied in detail, there are currently very few morphometric data available for subglacial pillow mounds, ridges, and sheets (Figures 6 and 7). They generally have among the lowest volume:area ratios in the data set, although the data are biased toward the sheet-like examples, which will always have relatively high outcrop areas. Aspect ratios are also very low, comparable only to subglacial sheet-like sequences (Figure 7), and subject to the same caveat.

Tephra Mounds and Ridges

Tephra mounds and ridges have been described for subglacial volcanoes of mafic and felsic compositions. They vary from conical edifices or mounds to linear ridges. Mafic examples are by far the commonest. They are comparatively steep-sided and, when erupted from fissures, form prominent ridges with multiple summit peaks (Figures 10 and 12). The ridge-like occurrences were called *tindars* by Jones (1969; also adopted by Hickson, 2000), an etymologically incorrect use of the Icelandic plural word (*tindur*) meaning pinnacles or summits (singular *tindur*). Its usage was extended informally by Smellie (2000) to encompass indiscriminately any subglacially erupted tephra piles, whether in mounds or ridges. A 'tindar phase' of subaqueous explosive eruptive activity would thus relate to the tephra-dominated cores of edifices that subsequently developed into tuyas. It may be preferable to refer to the landforms nongenetically as either tephra mounds or ridges according to their outcrop morphology (specifying subglacial to indicate eruptive environment). However, *tindar* should be restricted to occurrences (either ridges only, or else both ridges and mounds if a wider definition is preferred) for which a subglacial eruptive origin can be demonstrated. Since they form due to the explosive interaction of magma with water (meltwater in the case of glaciovolcanic eruptions), those erupted from

Figure 6 Morphometric data for subglacial volcanic landforms: volume versus area.

central vents may also be described nongenetically as simple tuff cones rather than tephra mounds.

The structure and lithofacies of felsic tephra mounds and ridges are not well described so far, except where they occur below a subaerial lava cap in tephra-dominated felsic (rhyolite) tuyas (Stevenson et al., 2011; Tuffen et al., 2002b). However, they also frequently occur without a lava caprock (e.g., in the Kerlingarfjöll rhyolite complex, central Iceland; Figure 13). They form relatively steep-sided pale-colored successions, commonly with numerous, sometimes voluminous craggy syneruptive felsic intrusions (Stevenson et al., 2011; Tuffen et al., 2007, 2009).

The tephra mounds/ridges have much lower volume:area ratios than the mafic and felsic tuyas, with ratios only lower in the subglacial sheet-like sequences and felsic domes (Figure 6(b) and 6(c)). They also extend to lower aspect ratios than the mafic tuyas on the length versus height diagram, which emphasizes the fissure-related aspects of the tephra landforms (Figure 7(a)). Most of the felsic tephra mounds also have higher aspect ratios than mafic examples, although there are too few data to be definitive (Figure 7(a) and 7(b)). In the width versus height diagram (Figure 7(b)), the tephra mounds/ridges show similar aspect ratios to compositionally analogous tuyas: that is, mafic tephra mounds/ridges with

Figure 7 Morphometric data for subglacial volcanic landforms: (a) height versus length; and (b) height versus width (aspect ratio). Symbols as in Figure 6.

Figure 8 Examples of tephra-dominated felsic tuyas in Iceland. (a) Raudufossafjöll. The summit rises approximately 400 m; (b) Hottur (at right) and unnamed peak, Kerlingarfjöll. Both peaks rise approximately 350 m.

mafic tuyas, and (less well defined) felsic mounds/ridges with felsic tuyas. However, the two landform categories (mounds vs. tuyas) are morphologically very different, with the flat tops of tuyas being the most prominent difference.

The distribution of subglacial mafic tephra mound data overlaps greatly with data for subaqueous mafic tuff cones erupted in unconfined, nonglacial settings, although displaced somewhat to the higher aspect ratio side (Figure 14(a)); subglacial felsic examples have higher aspect ratios than their nonglacial counterparts, but both felsic data sets are still very small. Felsic tephra mounds generally have greater volume:area ratios than their mafic counterparts, irrespective of a glacial or nonglacial setting (Figure 14(b)). The degree of overlapping data for mafic glacial/nonglacial mounds/cones is greater than anticipated since the subglacial examples are predicted intuitively to be generally taller as a consequence of a combination of effects (Smellie, 2009), including:

1. Buttressing of tephra by the confining ice walls (illustrated by Smellie, 2000, Figure 5).
2. Rapid early diagenesis and lithification of the warm wet tephra pile, which may be buffered at several tens of degrees celsius for a substantial period (Gudmundsson et al., 2004), particularly by coeval high-level intrusions.
3. Glacial erosion and oversteepening of the indurated volcano flanks once activity has ceased (Figure 12).

Examination of subglacial examples in Iceland seems to support this prediction. Those tephra landforms shown in Figures 10 and 12 are characterized by steep flanks that frequently cut across stratification in the indurated tephra, which contrasts with associated (underlying) coeval pillow mounds/ridges. By contrast, subaqueous tuff cones formed in unconfined marine or (nonglacial) lake settings generally have lower-gradient asymptotic flanks with surfaces parallel to bedding rather than cross-cutting, because of the long run-out distances possible in unconfined settings (Figure 15). A possible explanation may be that the measured widths of the subglacial

Figure 9 Examples of lava flow-dominated felsic tuyas in British Columbia, Canada. (a) The table (approximately 300 m); (b) Little Ring Mountain (approximately 280 m). Photograph (a) by Cathie Hickson and photograph (b) by Melanie Kelman.

examples are incorrect and inadvertently combine other landforms. Since most of the subglacial examples used in the dataset were culled from the literature, this may come about if the tephra mounds/ridges were constructed on pillow lava mounds (with low aspect ratios) if (1) the pillow lava piles

(commonly obscured by scree) were incorrectly mapped as tephra, or (2) tephra incompletely drapes the underlying, much lower-profile, pillow mounds and incorporates their form, thus creating a misleading composite landform, not one constructed solely by tephra.

Felsic Lobes and Domes

Several steep-sided subglacially erupted andesite, dacite, rhyolite, and trachyte–phonolite lavas with characteristic fine-scale prismatic jointing have been described from British Columbia and Iceland (Edwards and Russell, 2002; Kelman et al., 2002; Tuffen et al., 2002a,b). The radiating joint patterns and associated glassy chilled surfaces are interpreted as ice-contact features, within a subglacial vault. Together they define the original landform shapes, which may be conical, lobate, dome-like, or irregular (Figure 16). Associated fragmental volcanic lithofacies are usually uncommon.

Meltout tills and reworked volcanic sands and gravels are present in an Icelandic example together with ashy-matrix breccias.

The felsic lobes and domes have low volumes relative to their areas (Figure 6(c)) and they appear to have somewhat higher aspect ratios than many of the mafic subglacial volcanic landforms (Figure 7). Conversely, their aspect ratios are effectively indistinguishable from those of most other felsic landforms (i.e., felsic tuyas and tephra mounds).

Subglacial Sheet-Like Sequences

These were also called subglacial ‘sheet flow’ sequences by Smellie (2001) but were renamed subglacial sheet-like sequences by Smellie (2008) to incorporate nongenetic terminology. They are relatively thin deposits, which, as their name suggests, either form narrow, sinuous, anastomosing low outcrops, which are sometimes esker-like (Mathews, 1958; Smellie and Skilling, 1994), or else lobe- or sheet-like features (Smellie, 2008). However, the profile, overall shape, and dimensions of an outcrop will depend on the topography of the underlying bedrock (e.g., incised valley), erupted volume of magma and discharge rate (Loughlin, 2002). Most of the published examples are basaltic, but Edwards and Russell (2002) have described a few trachyte and phonolite examples in British Columbia and there are scarce rhyolite occurrences in Antarctica (Smellie et al., 2011a).

At least two different types of sheet-like sequence can be distinguished, referred to as Mt Pinafore and Dalsheidi types (Smellie, 2008). Their distinction is based on comparatively subtle differences in lithofacies and sequence architecture that have a large impact on their inferred modes of emplacement. It is unclear yet if those differences impact significantly on the resultant landforms and they are provisionally considered as a single landform group here. The differences have important implications for interpreting original ice sheet thicknesses (Smellie, 2008). Unlike all the other subglacial volcanic landforms described in this article, the sheet-like sequences are strata formed away from the erupting vent(s) (i.e., they are ‘outflow facies’) rather than

Figure 10 View and explanatory sketch, looking north from Kalfstindar (Iceland) showing contrasting subglacial mafic volcanic landforms, including steep tephra ridges, a tuya, and low-lying smooth-surfaced pillow mounds.

Figure 11 Extensive pillow sheet (dashed-line outcrop) at Thorisvatn, Iceland. The prominent ridge in the foreground is a pillow ridge. Photograph by Snorri Snorrason.

Figure 12 View looking south along the pinnacled ridge crest of Kalfstindar, a mafic tephra ridge in Iceland. Note the very steep sides of the ridge, which cut across tephra bedding in the deposit. The ridge rises approximately 250 m above the surrounding plain. The low subdued mounds in the foreground at right are pillow mounds.

volcanic edifices. The few source vents identified so far are simple pyroclastic cones, undiagnostic, in themselves, of a subglacial setting. The full range of source edifices has probably not been identified.

Subglacial sheet-like sequences range from only a few tens of meters thick to a few hundred meters, with widths up to several kilometers. A wide range of examples has been described in Iceland, Antarctica, and British Columbia (e.g., Kelman et al., 2002; Loughlin, 2002; Smellie, 2008; Smellie et al., 1993, 2011a). There are no published whole-outcrop-scale photographs of the sheet-like sequences since the majority described so far form multiple stacked units that together construct large stratovolcanoes. The morphology is unlikely to be sufficiently distinctive to be identified as glaciovolcanic without detailed lithofacies studies.

Not surprisingly, the sheet-like sequences have the lowest aspect ratios of any subglacial volcanic landform (other than subglacial pillow sheets), and they have a distinctive combination of very high area combined with low volume which,

Figure 13 Examples of felsic tephra mounds/ridges at Kerlingarfjoll, Iceland. (a) Looking west to Ogmundur from Hottur; the low mounded ridges at center-left are tephra mounds located along fissures. Ogmundur, at right, is a lava flow-capped felsic tuya that has been eroded to form the present prominent conical peak; (b) subdued, fissure-aligned, multiple overlapping felsic tephra mounds; Rodull.

however, is only slightly different from area:volume ratios for subglacial lobes and domes (Figures 6(c) and 7).

Influence of Glacier Thermal Regime on Subglacial Volcanic Landforms

All of the foregoing is based on an analysis of subglacial, mainly monogenetic, volcanic landforms that were created by eruptions beneath glaciers and/or ice sheets with wet-based (i.e., temperate or subpolar) thermal regimes, apart from aa lava-fed deltas that constructed several large polygenetic shield volcanoes under cold-based (i.e., polar) ice in northern Victoria Land but which probably had only a small influence on their morphometry (Smellie et al., 2011a). Thermal regime is important. It determines the hydraulics of an ice system, which, in turn, strongly influences the lithofacies, sequence architecture and, thus, the landforms ultimately constructed (e.g., Björnsson, 1988; Smellie, 2000, 2001, 2009). Wet-based glaciers are dominant on Earth today, except in parts of the Greenland and Antarctic ice sheets, so the results of the landform analysis in this article are likely to have wide application. There are different consequences for volcanic landforms constructed within a cold-based ice sheet or glacier (i.e., one that is frozen to its bed; Smellie, 2009). In those, water cannot escape subglacially, either in conduits or thin films. Any meltwater created by a subglacial eruption in cold-based ice will therefore be confined in a vault overlying the vent. The system will

Figure 14 Morphometric data for subglacial and nonglacial tephra mounds/ridges: (a) width versus height; and (b) volume versus area.

Figure 15 Sketch sections showing the impact of eruptive environment on the morphology of a large tuff cone. (a) An ice sheet is reconstructed. The eruption might have melted a space 3 km in diameter, as sketched. The thermal energy would have been focused in the central parts of the edifice (high heat flow in the vent(s)) and the high thermal inertia of the tephra pile would likely have prevented the melting of a significantly larger space during the eruption. The proximity of an ice sheet would have impinged on the growth of the edifice by buttressing effects of the ice walls (not illustrated), thus leading to an edifice with much steeper flanks, which is not the case. (b) An unconfined marine setting is shown, which is more consistent with the outcrop and can easily explain the presence of isolated outcrops of tephra behind topographical barriers (sketched at left) that cannot have formed had an ice sheet been present at the time. Sections based on a 600 m-high, mafic tuff cone on James Ross Island, Antarctica, which was erupted in a marine (i.e., nonglacial) setting approximately 660 000 years ago. Reproduced from Smellie JL, McArthur JM, McIntosh WC, and Esser R (2006) Late Neogene interglacial events in the James Ross Island region, northern Antarctic Peninsula, dated by Ar/Ar and Sr-isotope stratigraphy. *Palaeogeography, Palaeoclimatology, Palaeoecology* 242: 169–187.

Figure 16 Example of a felsic dome at Ember Ridge northwest, British Columbia, Canada. Despite the prominent post-eruptive erosion, the original dome-like morphology can be reconstructed (broadly following the curved skyline) using the orientations of the prominent columnar cooling joints in the outcrop, which grew perpendicular to the original confining ice surface. Photograph by Melanie Kelman.

ultimately overflow as volcanic mass (magma) is added and the water is displaced. The lower temperatures of cold-based glaciers also strongly influence the ice rheology, which is stronger and deforms much more slowly. The energy requirements for melting are also different. Since more energy is needed than in wet-based systems, simply to bring the ice temperature up to the melting point, the ice walls of a vault or lake will recede more slowly than in a wet-based ice sheet. As a consequence of these combined characteristics, the vault or lake will not enlarge so rapidly as in wet-based ice. The volcanic products will rapidly fill it and spill out to override the surrounding ice sheet surface. Moreover, because of the high thermal inertia of magma and insulating properties of any underlying autobreccia rubble, any supraglacial lava flows may be capable of traveling considerable distances without melting deeply into the underlying ice (Wilson et al., 2012). The edifices will also be buttressed by the slowly receding ice walls, presumably leading to even taller constructs than are possible in wet-based ice, although these will be liable to postglacial gravitational collapse and consequent modification of the edifice shape (e.g., Komatsu et al., 2007).

Mafic tuya

Felsic tuya, tephra dominated

- | | |

Figure 17 Drawings illustrating the influence of glacier thermal regime on the construction, lithofacies and morphology of mafic and felsic tuyas. (a) Wet-based (temperate or subpolar) glacier regime. (b) Cold-based (polar) glacier regime. The principal differences are shorter lava-fed deltas and taller edifices in cold-based ice compared with those formed in wet-based ice. Reproduced from [Smellie JL \(2009\)](#) Terrestrial sub-ice volcanism: landform morphology, sequence characteristics and environmental influences, and implications for candidate Mars examples. In Chapman MG and Keszthely L (eds.) *Preservation of Random Mega-Scale Events on Mars and Earth: Influence on Geologic History*, vol. 453, pp. 55–76. Geological Society of America Special Papers.

The overall effects of eruptions under ice sheets with differing thermal regimes can, therefore, be broadly predicted and the main results for mafic and felsic tuyas are shown in [Figure 17](#). However, in the absence of any data for monogenetic volcanic landforms constructed beneath cold-based ice sheets, it is currently impossible to provide any real morphometric dimensions with which to compare and contrast with analogous landforms associated with wet-based ice sheets.

Evidence of Glacier Recession

P M Colgan, Grand Valley State University, Allendale, MI, USA

Introduction

Today, we live in an age of global glacier recession. The retreat of glaciers and ice sheets worldwide provides unequivocal evidence of climate change and has serious implications for sea-level rise and landscape change in mountainous regions and high latitudes. Many mountain glaciers could disappear in the twenty-first century.

Glacier recession is the stepwise retreat of the terminus of a glacier or ice sheet toward its source area. This occurs when more ice is melted near the terminus in the ablation zone than can be replaced by ice flowing down the glacier from the accumulation zone. Glacier recession usually follows rising air temperatures because an increase in the elevation of the equilibrium line forces the glacier to attempt to reach a new mass balance by decreasing the area of its ablation zone. Glacier recession may also occur because of a decrease in snowfall in the accumulation zone or because of an increase in solar radiation. This also raises the equilibrium line and forces glacier recession. Ablation rates are commonly an order of magnitude higher than accumulation rates; therefore, changes in air temperature usually cause more dramatic changes in glacier areas than do changes in snowfall. Glaciers retreat in a regressive fashion because glacier ice is always actively flowing toward the terminus to replace what is melting. Because glaciers, especially small mountain glaciers, are sensitive to air temperature, snowfall, and solar radiation, both past and present glacier recessions are excellent indicators of climate change. Glaciers may also retreat by widespread downwasting if the terminus is cut off from the accumulation zone as a result of topographic effects or stagnation of ice following a glacier surge. (See Paterson (1994) for a detailed explanation of glacier mass balance and glacier surges.)

Direct observations, field surveys, oblique and aerial photography, and remotely sensed data are the primary evidence for historic glacier recession during the late Holocene. A careful analysis of data gathered in a series of years can provide evidence of both the magnitude and rate of glacier recession. Numerous studies have quantified the rate of glacier recession over the last 50–400 years in nearly every region of the world (e.g., Dyurgerov and Meier, 2000; Grove, 1988; Meier et al., 2003). In the past decade, entirely new methods based on synthetic aperture radar (SAR), laser altimetry or LIDAR (light detection and ranging), and satellite-based gravity measurements have revolutionized the way mass balance is measured in the largest glaciers, including the Antarctic and Greenland ice sheets.

The mapping of landforms and sediments in combination with absolute dating methods are used to determine the magnitude and sometimes the rate of late Pleistocene and Holocene glacier recession. Landforms that can be used to reconstruct the former glacier terminus include moraines, subglacial landforms, eskers, and outwash plains. There are many different types of moraines, which are ridges of glacial sediment formed along the

terminus (end moraines or recessional moraines) or sides of a glacier (lateral moraines). These landforms contain information about both the extent and style of past glaciers. Subglacial landforms such as drumlins, flutes, and striae are commonly exposed during glacier recession and record ice flow direction. Stream sediment deposited in front of, or on top of, the ice produces ice-contact features, outwash plains, fans, and channels. Many of these landforms can be dated with radiocarbon methods or newer methods such as cosmogenic radionuclide exposure and optically stimulated luminescence dating. What follows is a summary of some of the historic and geomorphic evidence for glacier recession and the implications for climate and glacier dynamics.

Evidence for Late Holocene Glacier Recession

Glaciers provide important spiritual, aesthetic, and utilitarian resources for human populations. In many parts of the world, glaciers provide economic benefits through water resources, hydroelectric generation, tourism, and wildlife habitat. The current recession of glaciers has important implications for the future of these resources. Glacier recession also contributes significantly to accelerating global sea-level rise (see World Glacier Monitoring Service report *Global Glacier Changes: Facts and Figures*, <http://www.grid.unep.ch/glaciers/>).

Mountain glaciers all over the world are in full retreat threatening natural resources and providing unequivocal evidence of climate change (Figure 1). About 100 glaciers worldwide have been monitored continuously for their net mass balance for the last 30 years by direct field measurements of accumulation and ablation. Mass balance for a glacier is determined by estimating the total accumulation and ablation in cubic meters of water equivalent. Net mass balance is the change in volume of water equivalent divided by the total area of the glacier. It is commonly reported in millimeters of water equivalent. According to the World Glacier Monitoring System, in the last year reported (2009), 83 of 99 glaciers in this sample decreased in mass, and at least some glaciers have completely disappeared in the last few years. Most years for which we have data show the same trend. The mean net cumulative mass balance for 30 representative glaciers in nine regions shows a decrease in mass for every year except three (1983, 1987, and 1989) in the period 1980–2009, and the three positive years were barely positive (see <http://www.geo.unizh.ch/wgms/>). Unfortunately, most of these are small glaciers and the distribution is weighted toward the Northern Hemisphere and Europe. Even so, it is clear we live in a period dominated by a global glacier recession.

Recession of mountain glaciers adds a significant volume of water to oceans and is an important factor in current sea-level rise (Meier et al., 2003). Dyurgerov and Meier (2005) estimated that there are over 160 000 mountain glaciers and ice caps with a total area of 685 000 km². This does not include the

Figure 1 Examples of glacier recession as shown in historical photographs. (a and b) McCall Glacier in 1958 and 2003. This is a small valley glacier located in the Brooks Range of northern Alaska. Photos by Austin Post (1958) and Matt Nolan (2003).

ice sheets of Antarctica and Greenland. Melting of these mountain glaciers alone will likely contribute a minimum of between 18 and 37 cm in sea-level rise by the year 2100 (Bahr et al., 2009). This is in addition to what the ice sheets may contribute in the future.

Glacier monitoring via remotely sensed data is a commonly used method to examine glacier change (Rignot et al., 2003). The Global Land Ice Measurements from Space (GLIMS) sponsored by the United States Geological Survey, the National Snow and Ice Data Center, and academic researchers is currently developing a database of glacier changes using ASTER satellite images compared to other data sources. Monitoring of glacier recession has and will continue to play an important role in understanding global climate change. The current GLIMS system contains outlines for about 60 000 individual glaciers, about one-third of all the known glaciers.

The Greenland and Antarctic ice sheets contain at least 60 m of equivalent sea-level rise. Until very recently, little was known

Figure 2 Mass loss from Greenland Ice Sheet between 2002 and 2008 from the GRACE Mission Reproduced from Cazenave A and Chen JL (2010) Time-variable gravity from space and present-day mass redistribution in the Earth system. *Earth and Planetary Science Letters* 298(3–4): 263–274. After Velicogna I (2009) Increasing rates of ice mass loss from the Greenland and Antarctic ice sheets revealed by GRACE. *Geophysical Research Letters* 36: L19503. <http://dx.doi.org/10.1029/2009GL040222>.

about the mass balance of these ice sheets. Recent satellite and airborne missions all indicate that both the Greenland and Antarctic ice sheets are losing mass. The GRACE mission (gravity recovery and climate experiment) beginning in 2003 has provided estimates of mass changes in both ice sheets. Greenland appears to be shrinking rapidly and the mass loss in the most recent period (2006–2009) appears to have accelerated from earlier in the decade (2002–2005). The most recent mass loss appears to be between 267 and 286 Gt year⁻¹ compared to 104–144 Gt year⁻¹ in the earlier period (Figure 2). As per GRACE data, estimates for the rest of Antarctica are complicated by glacial rebound, but they also indicate mass losses. (See Cazenave and Chen (2010) for a complete description of GRACE mission applications.) The most recent SAR data combined with GRACE data indicate that the West Antarctic ice sheet lost ice between 2002 and 2008 (Sasgen et al., 2010).

Besides direct measurements of mass balance changes, many more glaciers have been monitored for terminus position by means of direct observations, photographs, and remotely sensed data (Figure 3). Glacier recession has been reported in nearly every region of Earth (e.g., Cook et al., 2005; Dyurgerov and Meier, 2000; Meier et al., 2003; Rignot et al., 2003). Oerlemans (2005) used 169 glacier retreat records from around the world to reconstruct mean global temperature change over the last 400 years. This climate record extracted from glacier recession records approximated global temperature reconstructions based on other independent paleoclimate proxy records. Other studies show that glacier recession has accelerated in the last two decades of the twentieth century (Dyurgerov and Meier, 2000; Meier et al., 2003). This most recent global glacier recession began at the end of the Little Ice Age. The Little Ice Age was a period of cooler global temperatures that began in the late Middle Ages and ended in the last half of the nineteenth century (Grove, 1988). Since then, we have seen an acceleration of warming during the late twentieth century and this has led to a quickening in the pace of modern glacier recession.

Global sea-level rise since 1900 is estimated to be between 13 and 17 cm or $\sim 1.3\text{--}1.7\text{ mm year}^{-1}$ assuming a linear trend fitted to tide gauge data and satellite measurements. (See Cazenave et al., 2008 for a recent synthesis of global sea-level rise.) This rise is thought to be about half the result of mountain glacier melting and half due to the rise of sea surface temperatures leading to expansion of sea water. Recent satellite data suggest that the rate during the period 1993–2008 is almost twice the long-term rate or between 3.1 and 3.4 mm year^{-1} . Sea-level rise over the next 100 years could be even higher (up to 75 cm) depending on the rate of climate warming, the response of mountain glaciers and ice sheets, and the amount of warming of sea surface waters. These estimates assume that glaciers and ice sheets melt in a progressive fashion without a partial or total collapse of the marine-based West Antarctic ice sheet or parts of the Greenland ice sheet. If the West Antarctic ice sheet were to collapse, it could add another 3–5 m of sea-level rise in perhaps as little as a few hundred years. Rapid sea-level rise has dire implications for societies as a large proportion of the world's population lives close to the sea. Monitoring small mountain glaciers and ice sheets is necessary to help quantify the volume of the water being added to the oceans as well as to monitor regional climate. Current and future satellite remote sensing programs such as GRACE and the future IceSat II missions are critical to the monitoring of glacier and ice sheet recession.

Modern Glacier Recession and Geomorphology

As glaciers retreat, they expose landscapes that were only recently covered by ice. This provides an excellent opportunity to explore and understand how glacial landforms and sediments

Figure 3 This false-color image shows the Gangotri Glacier, located in the Uttarkashi District of Garhwal Himalayas, India. Gangotri Glacier is one of the largest in the Himalayas and is a source for the Ganges River. The glacier is currently 30.2 km long and between 0.5 and 2.5 km wide. Gangotri Glacier has been receding since 1780, although studies show that its retreat accelerated after 1971. (Please note that the contour lines drawn here to show the recession of the glacier's terminus over time are approximate.) Over the past 25 years, this glacier has retreated more than 850 m, with a recession of 76 m from 1996 to 1999 alone. Source: NASA (http://earthobservatory.nasa.gov/Newsroom/NewImages/images.php3?img_id=16584).

are formed during glacier recession. An excellent example of recent glacier recession is the well-studied Breiðamerkurjökull of southeastern Iceland (Evans and Twigg, 2002). This is a large temperate outlet glacier that drains the ice cap Vatnajökull (Figure 4). Breiðamerkurjökull has retreated between 4 and 5 km since 1894 AD (Figure 5). This works out to an average recession rate of approximately $40\text{--}50\text{ m year}^{-1}$ for the last 100 years. While recession has been the overall trend, the glacier did not retreat every year and in fact advanced or remained steady in the periods of 1950–55, 1968–73, and 1975–87. A large end moraine was formed during and after Breiðamerkurjökull reached its Little Ice Age maximum some time between 1886 and 1890. After about 1894, the glacier began to retreat from this Little Ice Age moraine. Breiðamerkurjökull continues to retreat like most other glaciers in Iceland.

The deglaciated foreland in front of Breiðamerkurjökull displays an interesting and varied assemblage of glacial landforms and sediments (Figure 6) that have been mapped in detail by Evans and Twigg (2002) and earlier workers (see references in Evans and Twigg, 2002). The most

Figure 4 This image shows the Vatnajökull ice cap as it appears in late summer. Vatnajökull covers an area of about 8100 km^2 and is the largest ice cap in Europe. One can see how the glacier's accumulation area is still covered in snow. Along the ice cap margin, one can see outlet glaciers that drain the main ice body. Most of the outlet glaciers show up as dark. This is because in the ablation zone, all of the previous winter's snow has melted by the end of summer, and bare ice shows up as dark. One can also see medial and lateral moraines on some of the outlet glaciers. Along the left margin of the photo, one can see some of the other ice caps in Iceland; Hofsjökull in the upper left and Myrdalsjökull in the lower left. The red areas in this false-color image are those areas covered with vegetation. Dark areas are lava fields and water. The large dark area between the ice cap and the coast is the sandur plain of Skeiðarárjökull, one of the largest outlet glaciers that drain Vatnajökull. Some areas along the coast have a bluish tint. This is meltwater carrying silt and discharging into the North Atlantic. (Landsat MSS image – USGS.)

conspicuous of these landforms are numerous small push moraines (Figures 7 and 8). Push moraines are small ridges that are made up of subglacially deposited till plus some outwash deposited in late summer. Ridges are commonly less than 5 m high and 10 m wide (Boulton, 1986). They can be traced in excess of 3 km and commonly have a saw-tooth pattern that reflects their formation along the crevassed terminus (Figures 7 and 8). They tend to be asymmetric in cross-sectional profile with a shallower proximal and steeper distal flank. In late winter (mid-April–mid-May), ablation is very low near the terminus of Breiðamerkurjökull. Because of this factor, the terminus of the glacier advances up to a few meters. This winter readvance pushes up material in front of the ice, forming a push ridge. In summer, the terminus retreats because of the high ablation rates in this part of south Iceland ($\sim 10 \text{ m year}^{-1}$). If the overall retreat in summer is greater than the next year's winter readvance, a small push moraine is preserved. Push moraines may coalesce when a particular year's readvance is more extensive than the previous winter's. Sediment may also be squeezed from underneath the ice margin to form small push ridges. At Breiðamerkurjökull, small push moraines have formed nearly every year since 1965 on the west lobe of the glacier (Figures 7 and 8). Because these ridges can be demonstrated to have formed annually or semiannually, they have

sometimes been called 'annual moraines.' Similar ridges have been exposed by recent glacier recession in Norway, Svalbard, Baffin Island, the Canadian Rockies, Canadian Arctic, southeastern Alaska, and New Zealand.

Figure 6 Vertical aerial photograph of the recently deglaciated area in front of the eastern lobe of Breiðamerkurjökull, south Iceland. Features visible include fluted till surface (f), small push moraines (p), larger end moraines (e), and outwash plain (o) (Landmaelingar Islands and University of Glasgow, 1998).

Figure 5 Quicktime movies of the recession of Breiðamerkurjökull from 1973 to 2000. Source: NASA (<http://svs.gsfc.nasa.gov/search/Keyword/Breidamerkurjokull.html>).

Figure 7 Vertical aerial photograph of the deglaciated surface in front of the western lobe of Breiðamerkurjökull, south Iceland. Features visible are fluted till surface (f) and small push moraines (p) (Landmaelingar Islands and University of Glasgow, 1998).

Larger ridges of glacial sediment up to tens of meters high and hundreds of meters wide formed during more extensive and long-lived readvances or still-stands in the terminus, which commonly results in the stacking and bulldozing of subglacial and proglacial sediments. The larger recessional moraines in front of Breiðamerkurjökull formed during still-stands of the terminus and others are older features that have been overridden by the glacier as it reached its Little Ice Age maximum position. Some of these larger recessional moraines show evidence for the presence of buried ice in the form of hummocky topography. Hummocky topography forms as buried ice within the moraine melts and causes collapse of the overlying sediment.

Flutes and drumlins make up a continuum of streamlined landforms that form under temperate glaciers that are sliding over a temperate bed (Boulton, 1987). Commonly, obstructions such as boulders or rock outcrops will form cavities under the ice (Figure 6). Subglacial sediment may be deformed into these cavities forming a fluted terrain under the ice margin. Larger obstructions and heterogeneity in the subglacial sediment will lead to the formation of streamlined hills called drumlins. At Breiðamerkurjökull, a fluted till surface underlies the small push moraines and larger recessional moraines (Figures 6 and 7). Small drumlins are also present in the landscape. An important observation is that some of the flutes end in individual push moraines (Evans and Twigg, 2002). This indicates that fluted terrain was being formed during recession and that small push ridges and flutes are genetically related. However, drumlins appear to be related to the position of ice at the Little Ice Age maximum and not to recessional positions. Recently, newly formed drumlins have been observed on a recently deglaciated surface in front of Múlajökull, a surge-type outlet glacier of Hofsjökull (Johnson et al., 2010). As modern glaciers retreat, we may learn more about how subglacial features such as drumlins are formed.

Eskers are another common feature in landscapes exposed by glacier recession. At Breiðamerkurjökull, several small eskers are being exposed as the terminus retreats (Figure 9). Numerous subglacial and englacial ice tunnels drain meltwater in summer from the surface of Breiðamerkurjökull. These tunnels can become filled with sorted stream sediments. Many of these tunnels occur englacially and the sediments filling them are poorly preserved because of reworking during the melting of the

underlying ice. Some subglacial tunnels are preserved as esker ridges. Sandar (or outwash plains) have formed at several levels in the proglacial area in front of Breiðamerkurjökull since the glacier began to retreat in 1900. On aerial photographs, the abandoned braided stream pattern can be seen on these surfaces (Figures 6 and 9).

Late Pleistocene Glacier Recession

At the end of the Pleistocene Epoch approximately 10 000 years ago, the great ice sheets that covered North America and northern Europe were rapidly melting. This glacier recession began about 21 000 ^{14}C years BP and accelerated after about 14 500 ^{14}C years BP. By 5000 ^{14}C years BP, the great ice sheets were gone (see Dyke and Prest, 1987 for maps of North America). Most of the evidence we have for the timing of this glacier recession comes from radiocarbon dating of wood, peat, shells, and other organic matter that accumulated on top of glacial sediments deposited during recession (see Dyke et al., 2002, for a recent summary). The timing of major readvances during the deglaciation comes from radiocarbon dated wood buried under till of the readvance phases. Perhaps the most well-known example is the Two Creeks forest bed in the Great Lakes region of the United States. At this site, numerous radiocarbon dates on wood show that ice advance (and the rising lake waters) killed the forest and buried it under a readvancing glacier and its till at about 11 850 ^{14}C years BP (Broecker and Farrand, 1963).

The Laurentide ice sheet, the largest of all the late Pleistocene ice sheets, produced a truly remarkable record of glacier recession along its southern margin in the northern United States. Many of the glacial features we see forming in southeastern Iceland today along the margin of Breiðamerkurjökull were being formed along the southern margin of the Laurentide ice sheet during the late Pleistocene deglaciation (Colgan et al., 2003; Evans, 2003a,b). By comparing landforms and sediments in Iceland with those that formed during the late Pleistocene, we can better understand how the late Pleistocene deglaciation progressed and how rapidly the terminus retreated across the landscape.

Central and southern Wisconsin, an area of roughly 40 000 km², exposes a unique record of glacier recession including landforms such as drumlins and flutes, small push moraines, recessional moraines, eskers, and outwash plains (Colgan, 1999; Colgan and Mickelson, 1997). The distribution of these landforms and their relationships to one another are nearly identical to those forming in southeastern Iceland today. One big difference is that landforms in Wisconsin cover an area hundreds of times larger than that covered in Iceland. Another important difference is the occurrence of features such as hummocky moraines and tunnel channels, features not common in Iceland. These are found along the maximum ice margin and indicate that supraglacial sediment cover and drainage of subglacial meltwater were important processes when ice was at its maximum late Pleistocene position (see Clayton et al., 1985). In the deglaciated foreland of Breiðamerkurjökull, hummocky topography is only a minor landform type and tunnel channels do not appear at all. This difference could be because unlike Breiðamerkurjökull, which

Figure 8 Small push moraines in front of Breiðamerkurjökull, south Iceland. Photograph by P.M. Colgan (September 2000).

Figure 9 Eskers (k) on the deglaciated foreland in front of Breiðamerkurjökull, south Iceland; outwash plain (o) (Landmaelingar Islands and University of Glasgow, 1998).

is a temperate glacier, these glaciers were polythermal glaciers. This would lead to a frozen margin interacting with permafrost and producing hummocky moraines (see [Evans, 2009](#), for a recent discussion of these landforms).

Small push moraines are common features in southern Wisconsin in the area once covered by the Green Bay lobe of the southern Laurentide ice sheet ([Figure 10](#)). These ridges are usually about 10–50 m wide and less than 2 m high. They are traceable over distances of up to 3 km and commonly overlap or cross-cut. Where ridges are well preserved, they appear to be spaced between 25 and 100 m apart. The ridges are superimposed on fluted and drumlinized terrain just as they are in Iceland. If we accept the hypothesis that these ridges formed annually or semiannually as the small push moraines in Iceland do, then they would indicate a retreat rate of about 50 m year^{-1} for at least hundreds of years between 15 500 ^{14}C years BP and 13 000 ^{14}C years BP. Some especially well-preserved ridges ([Figure 10](#)) are also described in northern Wisconsin, produced by the Wisconsin Valley sublobe of the Laurentide ice sheet ([Ham and Attig, 2001](#)). It is estimated that retreat rates were between 37 and 82 m year^{-1} when these ridges formed and ablation rates near the margin of the ice sheet must have been between 1.7 and 14.5 m year^{-1} . The common seasonal climate patterns both in Iceland and along the southern margin of the Laurentide ice sheet may have been the high summer ablation rates followed by a cold winter when ice could advance and push up a small ridge.

Larger recessional moraines are found along the southern margin of the Laurentide ice sheet and can be traced all the way from New York to the Dakotas. These moraines have a complex history reflecting sedimentation during both glacier advance and glacier recession. Many of the end moraines in Illinois, Indiana, southern Michigan, and Ohio are composed of stacked sequences of basal till, outwash, and lake sediment.

In Illinois, the very massive moraines are thought to have formed mainly by subglacial transport and deposition of deformable subglacial sediment that was being moved toward the terminus by rapidly flowing outlet glaciers perhaps fed by ice streams ([Johnson and Hansel, 1999](#)) with a thin cover of hummocky topography in the end moraine zone ([Curry et al., 2010](#)). In North Dakota, Minnesota, Wisconsin, and Northern Michigan, end moraines are very hummocky and indicate that ice near the margin became stagnant and was buried by thick supraglacial debris ([Ham and Attig, 1996](#); [Johnson and Clayton, 2003](#); [Johnson et al., 1995](#); [Parizek, 1969](#)). Using terminology introduced by [Gravenor and Kupsch \(1959\)](#), [Evans \(2009\)](#) interprets these moraines as ‘controlled moraines.’ He describes them as “supraglacial debris concentrations that become hummocky moraine upon deicing and possess clear linearity due to the inheritance of the former pattern of debris-rich folia in the parent ice.” This supraglacial material must have been elevated from the subglacial bed near the terminus because there are no nunataks that could have dropped debris onto this ice surface in the lowland terrain. Processes such as thrusting and shearing of basal debris as has been observed in subpolar glaciers may have been at work. Upon melting, which could have taken several thousand years, the complex topography of kettles, kames, and ice-walled lake plains formed.

Most of the deglaciated surface in Wisconsin is covered by drumlins and flutes. Other regions covered by extensive fields of drumlins include northcentral Minnesota, Michigan, New York, and New England. The subglacial landforms in these areas are covered by landforms formed during glacier recession such as push moraines, and larger recessional moraines ([Colgan et al., 2003](#)).

Ice-marginal Stagnation Along the Southern Margin of the Laurentide Ice Sheet

In areas along the lowland margins of the great ice sheets in North America and Europe, extensive areas of hummocky moraine suggest that at least in the ice-marginal zones of glaciers, ice wasted from the top down and became stagnant at the end of the last glaciations. Some of these zones were up to 20–40 km wide parallel to the flow direction of the glacier. Blocks of stagnant ice detached from active ice during glacier recession ([Evans, 2009](#); [Johnson and Clayton, 2003](#)). This probably indicates that polythermal glaciers interacted with permafrost. In the western Great Lakes region and the plains states of the United States, large hummocky controlled moraines suggest that ice near the margin was covered by supraglacial sediment and slowly melted out during deglaciation (see [Colgan et al., 2003](#)). Even in areas once thought to be dominated by temperate ice, recent evidence suggests that ice-marginal stagnation and down wasting occurred, forming a karstified landscape of shallow lakes and melting ice ([Curry et al., 2010](#)). The most common landforms produced by these phenomena are hummocks, ring forms, dump ridges, disintegration ridges, and ice-walled lake plains ([Colgan et al., 2003](#); [Evans, 2009](#); [Gravenor and Kupsch, 1959](#); [Johnson and Clayton, 2003](#); [Parizek, 1969](#)). In the Canadian Prairie region and plains region of the United States, there is evidence that large

Figure 10 (a) Small push moraines that may have formed annually during the recession of the Green Bay lobe between 15 500 and 13 000 ^{14}C years BP. (b) Small push moraines created by the Wisconsin Valley lobe in north-central Wisconsin during deglaciation. Reproduced from Ham NR and Attig JW (2001) Minor end moraines of the Wisconsin Valley Lobe, north-central Wisconsin, USA. *Boreas* 30: 31–41.

areas of debris-rich stagnant ice covered the landscape during deglaciation in the form of aligned hummocks, ring forms, and disintegration ridges (Gravenor and Kupsch, 1959; Parizek, 1969, and papers in Evans 2003a,b).

Hummocks are rounded knobs, hillocks, or mounds occurring in widespread tracts (Figure 11). Hummocks are usually described as round to oval in map view, 15–400 m in diameter, and spaced from 150 to 500 m apart. The local relief of hummocks is usually described as between 2 and 70 m with most less than 20 m. Hummocks have been classified into categories based on relief, but a continuum of size and form may also exist. A large area of hummocks is commonly called hummocky topography.

Ring forms are circular or doughnut-shaped forms that commonly form a continuum with hummocks. They can be thought of as small hummocks with a central depression. These forms are thought to have formed when stagnant debris-covered ice melts and deposited supraglacial sediment. Ice-walled lake plains form when ice becomes stagnant and meltwater ponds in sinkholes on top of the glacier. The water in the supraglacial lakes melts its way to the bed in areas of

supraglacial debris near the margin. Sediment moved by streams and gravity deposit sediment in these lakes. Lacustrine, fluvial, and deltaic sediment may completely fill the sinkhole formed in the ice. Upon the melting of surrounding ice, the sediment may completely collapse to form a hummocky topography or it may form a plateau of lacustrine sediment surrounded by an ice-contact ridge. Ice-walled lake plains have been described in Canada, North Dakota (Figure 12), Minnesota, Wisconsin, Iowa, and as high kames in southern New England. Ice-walled lake plains are also found in northern Europe in Denmark, Sweden, Germany, Poland, and Russia.

Disintegration ridges (or crevasse-squeeze ridges) are linear ridges from 1 to 10 m high and 10 to 100 m wide that probably form when sediment is dumped into or squeezed into crevasses in stagnant ice. They commonly show the control of a network of crevasses and may display a box work pattern where the original ice blocks outlined by longitudinal and transverse crevasses may be easily visualized. Disintegration ridges are found both in Canada and the northern United States, as well as in northern Europe. A dump-ridge is a pile of debris that forms along the margins of stagnant ice. These ridges are found both in front of stagnant ice bodies and behind large masses of stagnant ice. They have been described in Wisconsin and Minnesota and are probably common wherever stagnant ice was covered by supraglacial debris.

The key environmental factor in developing the features described above is stagnation of supraglacial debris-covered ice near the margin of a glacier during recession. Some have suggested that ice in a zone 2–40 km wide near the ice margin becomes covered by debris and is detached from the actively retreating ice (Ham and Attig, 1996; Johnson and Clayton, 2003; Johnson et al., 1995). This debris-covered ice may then take several thousand years to melt completely. Pleistocene ice-cored moraines in Siberia and in the Mackenzie Delta region of Canada are still melting out and producing topography similar to the forms described above thousands of years after glacier recession.

Estimated Rates of Glacier Recession During the Late Pleistocene

Many workers have attempted to calculate the rate of late Pleistocene ice sheet recession from radiocarbon dating and end moraine mapping. Many of the calculated rates of recession are similar to those seen in modern glaciers today. Kaplan (1999) estimated that the southeastern margin of the Laurentide ice sheet retreated at a rate of about 20 m year^{-1} for the period from 14 000 to 13 000 ^{14}C years BP based on radiocarbon dates and numerous small ridges that formed along a retreating tide-water glacier margin. Gustavson and Boothroyd (1987) compiled a table showing estimates of the glacier recession rates of the southeastern Laurentide ice sheet in southern New England. Most of the rates calculated for the early part of the deglaciation before 13 000 ^{14}C years BP were between 50 and 100 m year^{-1} . Rates of recession calculated from small push moraines in Wisconsin are also in the range of $50\text{--}100 \text{ m year}^{-1}$.

Much higher rates of glacier recession have been calculated for areas in which ice may have stagnated during deglaciation. Clayton et al. (1985) calculated recession rates as high as

Figure 11 A stereo aerial photo pair of an ice-walled lake plain in Montrail County, North Dakota (BAL-4V-9 and 10, USDA). Ring forms and hummocks surround the ice-walled lake plain.

2000 m year⁻¹ on some of the southwestern lobes of the Laurentide ice sheet. They explained these high rates by regional stagnation of ice lobes after a surge.

Implications of Evidence of Glacier Recession

Landforms and sediments produced during glacier recession provide scientists with a unique perspective on the reconstruction of past glacier recession. As demonstrated earlier,

one way to understand these events is by comparing modern glacier environments and processes to landscapes formed in the past. By these studies and comparisons of past and present events, we can interpret the magnitude and sometimes estimate the rate of glacier recession. The biggest limitation in estimating accurate glacier recession rates is the uncertainty in dating methods (500–1500 years for radiocarbon ages before 10 000 years BP) and the lack of organic material available for radiocarbon dating. A more fundamental problem is that average recession rates do not account for small advances

Figure 12 Stereo aerial photographs of an ice-walled lake plain in North Dakota.

during recession or still-stands. This can be clearly seen in Iceland where an average recession rate of $40\text{--}50\text{ m year}^{-1}$ for the period 1894–1998 clearly does not include documented still-stands and minor advances. Clearly, evidence for glacier recession can be used to both monitor modern glacier recession and reconstruct the style and rates of recession of past ice sheets, but it remains to be seen if we can directly compare modern rates with those of late Pleistocene glaciers.

Introduction

The earliest glacial landsystem-type investigations include those of [Speight \(1963\)](#), who mapped and grouped landforms according to common origin and age, and [Clayton and Moran \(1974\)](#), who linked process and form in assessing the spatial distribution of glacial features. Glacial landsystems per se were introduced by [Fookes et al. \(1978\)](#) to provide engineers with genetic classifications of glaciogenic landform–sediment assemblages and included the till plain, glaciated valley, and fluvio-glacial and ice-contact deposit landsystems. The component parts of landsystems are land units (e.g., drumlin or fluting field, Rogen moraine belt, and suite of recessional push moraines) and land elements (e.g., individual drumlins, flutings, eskers, kame terraces, and moraines), with the landsystem thus being a recurrent pattern of genetically linked land units. This was refined by [Eyles \(1983a,b\)](#), [Eyles and Menzies \(1983\)](#), and [Paul \(1983\)](#), who introduced the subglacial, supraglacial, and glaciated valley landsystems, and thereby emphasized the location of glaciogenic deposition as the principal factor in land-system classification. Recent developments in the glacial landsystem concept ([Evans, 2003a](#)) have addressed the complexity of glacial depositional environments and relate the variability in landform–sediment assemblages to both the location of deposition and the style of glaciation. Additionally, greater use is now being made of contemporary glacial environments, where landscape evolution can be monitored, to provide modern landsystem analogs for the interpretation of ancient glaciated terrain. Meticulous mapping of glacial landsystems also often informs us of the fact that the characteristics of glacier snouts have changed over the period that they have retreated from a landscape. This is manifest in either land-system overprinting, often associated with glacier readvance (e.g., [Krüger, 1994](#); [Wilson and Evans, 2001](#)), or spatial and temporal change, the latter referring to sequential changes in signature with distance along a single foreland or drainage basin (e.g., [Colgan et al., 2003](#); [Evans, 2011](#); [Evans et al., 2008, 2010](#)).

Landsystem Modern Analogs

Landsystem classifications of modern glacial environments, where landscape evolution can be monitored, provide analogs for the interpretation of ancient glaciated terrain ([Dyke and Savelle, 2000](#); [Evans and Twigg, 2002](#); [Gustavson and Boothroyd, 1987](#); [Kjær and Krüger, 2001](#); [Krüger, 1994](#); [Price, 1969](#)). This type of research on modern glaciers has led to the identification of landform–sediment suites indicative of specific styles of glaciation, including plateau ice fields ([Rea and Evans, 2003](#); [Rea et al., 1998](#)), arid polar glacier margins ([Fitzsimons, 2003](#)), and ice dynamics such as surging glaciers ([Evans and Rea, 1999, 2003](#)) and ice streams

([Clark et al., 2003](#); [Stokes and Clark, 1999, 2001](#)). Once a landform–sediment suite pertaining to a single period of glacier occupancy or activity can be identified, it often becomes possible to differentiate overprinted signatures and landscape palimpsests (e.g., [Clark, 1993, 1999](#); [Dyke and Morris, 1988](#); [Krüger, 1994](#); [Wilson and Evans, 2001](#)). Examples of some modern analogs are reviewed here, followed by a discussion of their application to ancient glaciated landscapes. The terrestrial examples used here are clearly not exhaustive, and the reader is directed to [Evans \(2003a\)](#) and [Benn and Evans \(2010\)](#) for a more comprehensive coverage of the wide range of glacial landsystems that have thus far been identified in both terrestrial and offshore settings.

Active Temperate Glacial Landsystem

Active temperate glacier margins are capable of forward momentum even during overall recession, and this is manifested in the small winter readvances that characterize receding outlet glaciers in places such as Iceland ([Boulton, 1986](#); [Krüger, 1995](#); [Sharp, 1984](#)). Details of the glaciology and associated sediment and landform production at the southern Icelandic glacier snouts are presented in numerous publications ([Benn, 1995](#); [Boulton, 1986](#); [Boulton and Eyles, 1979](#); [Boulton and Hindmarsh, 1987](#); [Evans and Hiemstra, 2005](#); [Krüger, 1985, 1993, 1994](#); [Sharp, 1984](#)), and it is from this expansive literature that a landsystem model for active temperate glaciers has been compiled ([Evans and Twigg, 2002](#); [Evans, 2003b, 2005](#)). This model recognizes three dominant depositional domains with characteristic landform–sediment assemblages ([Figure 1](#)). First, the marginal morainic domain consists of areas of extensive low-amplitude marginal dump, push, and squeeze moraines ([Evans and Twigg, 2000](#); [Evans et al., 1999](#); [Price, 1970](#)) often recording annual ice recession, although short periods of readvance or stability can produce larger push moraines due to stacking of submarginally frozen sediment slabs ([Evans and Hiemstra, 2005](#); [Krüger, 1985, 1993, 1994, 1996](#)), or dump, squeeze, and push mechanisms operating at the same location over several years. Second, the subglacial domain includes assemblages of flutings, drumlins, and overridden push moraines that occur between ice-marginal depocenters and are linked to subglacial deformation and lodgement processes ([Benn, 1995](#); [Benn and Evans, 1996](#); [Boulton, 1987](#); [Boulton and Hindmarsh, 1987](#); [Evans and Hiemstra, 2005](#); [Hart, 1995](#)). Third, the glaciofluvial and glaciolacustrine domain includes (a) the deposits of proglacial outwash streams that drain either away from glacier margins to produce sandur (outwash) fans or parallel to the margin to produce ice margin-parallel outwash tracts and kame terraces, (b) the glaciolacustrine depocenters that have developed in large lake-filled depressions uncovered by glacier recession, and (c) simple and complex anabranching eskers that often grade into recessional ice-contact fans and areas of pitted outwash. In addition to

Figure 1 The active temperate glacial landsystem. Landforms are numbered according to their domain: 1, morainic domain; 2, glaciofluvial domain; and 3, subglacial domain): 1a, small, often annual, push moraines; 1b, superimposed push moraines; 1c, hummocky moraine; 2a, ice-contact sandur fans; 2b, spillway-fed sandur fan; 2c, ice margin-parallel outwash tract/kame terrace; 2d, pitted sandur; 2e, eskers; 2f, entrenched ice-contact outwash fans; 3a, overridden (fluted) push moraines; 3b, overridden, readvance ice-contact outwash fan; 3c, flutes; and 3d, drumlins. The idealized stratigraphic section log shows a typical depositional sequence recording glacier advance over glaciofluvial sediments comprising (i) undeformed outwash; (ii) glaciectonized outwash/glacitectonite; (iii) massive, sheared till with basal inclusions of preadvance peat and glaciofluvial sediment; and (iv) massive sheared till with basal erosional contact. Modified from Krüger J (1994) Glacial processes, sediments, landforms and stratigraphy in the terminus region of Myrdalsjökull, Iceland. *Folia Geographica Danica* 21: 1–233; Evans DJA and Twigg DR (2002) The active temperate glacial landsystem: A model based on Breidamerkurjökull and Fjallsjökull, Iceland. *Quaternary Science Reviews* 21: 2143–2177; Evans DJA (ed.) (2003a) *Glacial Landsystems*. London: Arnold.

the three major depositional domains, anomalies are to be expected due to the signatures of erratic/noncyclic or site-specific processes, including jökulhlaup features (Fay, 2002; Maizels, 1997; Russell and Knudsen, 1999).

Glaciated Valley Landsystem

The glaciated valley landsystem was first compiled by Boulton and Eyles (1979) and Eyles (1983b) in order to encompass the landform–sediment associations produced by valley glaciers. Owen and Derbyshire (1989) highlighted the large volumes of supraglacial debris on Karakoram glaciers and illustrated the fact that valley glaciers do not always deposit clear, inset sequences of proglacially constructed latero-frontal moraines as depicted in the Boulton and Eyles (1979) model. Benn et al. (2003) subsequently demonstrated the huge variability in landform and sediment assemblages in highland settings due to their occurrence at every latitude on the Earth's surface, and they proposed a model that comprises a family of landsystems (Figure 2). Recurrent features identified by Benn et al. include (a) the strong influence of topography on glacier morphology, sediment transport paths, and depositional basins; (b) the important role of supraglacial debris sources; and (c) the rate of sediment transport from the glacier to the proglacial environment via the glaciofluvial system. Their family of landsystems lie on a continuum between the two extremes of 'clean' glaciers, with limited supraglacial debris, and debris-covered glaciers/rock glaciers. Additionally, the relief of upland landscapes often results in temporary lake production during glaciation, either by ice damming of valleys or by moraine

damming. The latter are potentially dangerous features in mountain terrain due to their tendency to catastrophically burst through moraine dams and produce glacial lake outburst floods (Cenderelli and Wohl, 2003; Clague and Evans, 2000; Kershaw et al., 2005). The different members of the glaciated valley landsystem family identified by Benn et al. (Figure 2) are defined by the efficiency of glaciofluvial transport between the glacier and its proglacial area. Efficient transport defines a 'coupled' landsystem association in which moraine development is limited and an outwash head/aggrading sandur (Kirkbride, 2000) is common, as typically occurs in the humid mountain ranges of Alaska and New Zealand. Inefficient transport defines a 'decoupled' landsystem in which repeated superposition of large moraines occurs around the margin of a debris-covered glacier, as is common in high-altitude, semiarid to arid mountain ranges such as the central and northern Andes and High Asia.

Plateau Ice Field Landsystem

Plateaus are the loci of glacier initiation and expansion during cooling events (Ives et al., 1975) and tend to be a haven for glaciers during interglacials and interstadials, depending on the latitude and altitude of the plateau and the global climate characteristics at the time (Manley, 1955; Rea et al., 1998). Precipitous drops at the margins of plateaus lead to the development of 'reconstituted glaciers' (Benn and Lehmkuhl, 2000) through dry calving at the plateau cliff edge (Gellatly et al., 1986). During the more advanced stages of local-scale glaciation, glaciers develop in the surrounding valley bottoms, and it

Figure 2 Constraints on landsystem development around valley glaciers, showing development pathways to four landsystem associations. is during this stage that the most significant landforms are likely to be produced; in most instances, the surrounding valleys contain the bulk of the landform–sediment assemblages used in reconstructing the former glacier cover (Rea

and Evans, 2003). On plateau summits, the thermal and dynamic properties of the ice determine the geomorphic signature, which in many instances, especially where ice was cold based, may be very subtle or nonexistent (Dyke, 1993).

Figure 4 A landsystem model for ice streams showing the four end members of marine-based and terrestrial systems, which are either isochronous/rubber stamped or time transgressive/smudged. Reproduced from Clark CD and Stokes CR (2003) Palaeo-ice stream landsystem. In: Evans DJA (ed.) *Glacial Landsystems*, pp. 204–227. London: Arnold, with permission.

The assemblage of landforms produced by plateau ice fields in the Canadian High Arctic, northern Norway, and Iceland has been used to compile a plateau ice field landsystem (Rea and Evans, 2003; Rea et al., 1998; Figure 3). Plateau summits may contain nothing more than deglacial meltwater channels cutting through preexisting regolith or blockfield if the former ice cover was cold based. Lateral meltwater channels produced by the retreat of outlet glaciers onto plateaus are characteristic of recession by cold-based ice (Dyke, 1993; Maag, 1969). Evidence for localized erosion by warm-based ice (e.g., striated bedrock and roches moutonnées, and the removal of blockfield) occurs in the topographic depressions at plateau edges where ice flow velocities increase due to drawdown into surrounding valleys. Moraines may also be found on plateau edges or leading onto the plateau from the surrounding valley

head outlets if warm-based conditions exist locally, but significant till covers do not form due to the commonly short transport distances to plateau outlets and the dynamics of the plateau ice cover (Evans et al., 2006a). If the ice is cold based throughout, lateral and frontal moraines will be found only in the valleys. Valley moraines tend to be dominated by large, cobble- to boulder-sized, angular material even where there is evidence of basal sliding, indicating that the dominant debris source is rockfall. Many latero-frontal moraines in the valley heads that surround the plateaus are ice cored and display within-valley asymmetry (Benn, 1989). This reflects the distribution of bedrock-free faces and the concomitant variability in rockfall/avalanche and debris flow activity. Active free faces may provide sufficient debris to produce supraglacial lateral moraines. In some circumstances, these may develop into

Figure 5 Paleo-ice stream imprints. (a) The imprint of ice stream shut down or the rubber-stamped imprint. (b) The overprinted sequence of a continuously operating ice stream during deglaciation or the smudged imprint. rock-glacierized ice-cored moraines that may persist after deglaciation of the valley heads (Evans, 2005). The valley floors are characterized by thin, generally patchy tills, which locally thicken in depressions.

Ice Stream Landsystem

Remotely sensed observations on the processes operating at the beds of ice streams in the Antarctic Ice Sheet (Kamb, 2001) combined with evidence of landform–sediment assemblages on the Antarctic continental shelf, across which ice streams formerly flowed, have informed recent compilations of paleo-ice stream landsystems (Canals et al., 2000). Ice streams are spatially restricted regions (arteries) of fast-flowing ice in an ice sheet and are readily identifiable by their surface structures and velocities. A landsystem model for ice streams has been developed by Stokes and Clark (1999) and Clark and Stokes (2003) based predominantly on the subglacial bedform evidence for fast-flowing ice and validated by glaciological data on modern ice streams (Figure 4). The bedform evidence comprises mega-scale glacial lineations (MSGs), which are elongate stream-lined ridges of sediment similar to flutes and drumlins and thought to be indicative of high strain rates and fast ice velocity. The pattern of subglacial bedforms should reflect the dominant flow patterns within an ice stream in that they should converge in an onset zone and lead into a much narrower and well-defined trunk zone where highly attenuated streamlined bedforms (MSGs) record the rapid velocity of the ice stream trunk. The higher elongation ratios of MSGs occur in the trunk rather than in the convergent onset zone, and the highest elongation ratios are in the central axis of the trunk. Additionally, elongation ratios in marine-terminating ice streams should steadily increase downstream toward the grounding line, but in terrestrially terminating ice streams, they decrease toward the outer margins of the lobate terminus. Ice streams also display abrupt lateral margins where fast ice abuts slower

moving ice. This is reflected in the subglacial bedform record, in which a high density of bedforms within the ice stream ceases abruptly. Sediment may concentrate at this boundary, producing an ice stream shear margin moraine (Dyke and Morris, 1988; Dyke et al., 1992; Stokes and Clark, 2002). At the terminus of ice streams, it should be expected that large depocenters will accumulate, such as submarine ‘till deltas’ (Alley et al., 1989; Vorren and Laberg, 1997) and grounding line wedges (Ó Cofaigh et al., 2003; Powell and Domack, 1995). Because ice streams switch on and off and dominant ice flow trajectories change during the life cycle of an ice sheet, ice stream imprints may crosscut each other (Dyke and Morris, 1988). Two end member landsystems are envisaged by Clark and Stokes (2003); Figure 5 to account for possible landform records of paleo-ice streams: (a) the ‘rubber-stamped’ imprint, produced when an ice stream imprint is produced at the same time and represents a snapshot of ice stream activity at a point in time when the ice stream switched off, and (b) the ‘smudged’ or overprinted, time transgressive imprint, produced when an ice stream operates throughout several cycles of advance and retreat or is continuously operating during margin retreat and earlier imprints are modified and overprinted by the younger ice flow patterns.

Applications of Modern Analogs to Quaternary Glacial Landscapes

Spatial and Temporal Change in Active Temperate and Polythermal Glacial Landsystems

Evidence of the recession of a former active temperate glacier lobe at the margin of the southwest Laurentide Ice Sheet has been reported by Evans et al. (1999, 2006b) and Benn and Evans (2006), manifest in the deglacial landforms of the McGregor Lake area of southern Alberta, Canada. Active temperate recession is recorded by numerous closely spaced,

Figure 6 The McGregor Lake moraine belt in Alberta, Canada: (a) glacial geomorphological map of the area showing three partially overprinted suites of moraines and associated landforms (reproduced from [Evans DJA, Rea BR, Hiemstra JF, and Ó Cofaigh C \(2006a\)](#) A critical assessment of subglacial mega-floods: A case study of glacial sediments and landforms in south-central Alberta, Canada. *Quaternary Science Reviews* 25: 1638–1667; [Evans DJA \(2009\)](#) Controlled moraines: origins, characteristics and palaeoglaciological implications. *Quaternary Science Reviews* 28: 183–208); (b) aerial photograph extract of the outermost moraine suite in (a), showing less continuous moraine ridges, numerous kettle holes, and no flutings in the lower right half of the image. The upper left half of the image shows part of the intermediate moraine suite and its larger and more continuous moraine ridges and lack of kettle holes.

Figure 8 (Continued)

low-amplitude moraine ridges that are inset by zones of flutings trending obliquely to individual moraine crests. This assemblage comprises the innermost of three overprinted 'landform suites' in a larger and more complex moraine belt (Evans, 2009; Figure 6(a)). The landform suites constitute a form of landsystem zonation and appear to record changing thermal regimes in the receding and occasionally readvancing ice sheet margin. In contrast to the innermost, active temperate suite, the outermost suite is characterized by less continuous moraine ridges, numerous kettle holes, and no flutings (Figure 6(b)). The terrain lying between the innermost and outermost suites contains some larger, more continuous moraine ridges, where densely spaced kettle holes are less common. Based upon these characteristics, the outermost suite is interpreted as the remnants of controlled moraine, produced at a time when the ice sheet margin was cold based, whereas the innermost suite appears to be consistent with the interpretation proposed by Evans et al. (2006b) that entails construction of recessional push moraines by a predominantly warm-based ice

margin. Evans (2009) has hypothesized that the intermediate suites of landforms relate to a period when ice-marginal conditions were changing from polythermal to temperate, and patchy permafrost led to the construction of larger push moraines in some areas.

Glaciated Valley Landsystem

The concept of a family of glaciated valley landsystems has been applied by Benn et al. (2003) to the Ben Ohau Range in New Zealand (Brazier et al., 1998). Holocene climate change in an area with a steep precipitation gradient has resulted in rising equilibrium altitudes and a concomitant response in glacial landsystem development due to altering debris supply and transport. Present-day landsystem distribution demonstrates the crucial role that aridity plays in local factors for landform development. The outwash-dominated landsystems of the major Mount Cook valley glaciers occupy large catchments to the north of the range. Whereas relatively clean Alpine

Figure 9 The Dubawnt Lake paleo-ice stream. (a) Satellite image of megascale glacial lineations indicating fast ice flow. (b) Map of the paleo-ice stream showing the extent of former onset zone, trunk, and terminal divergence overprinting earlier flow patterns. glaciers occupy the uplands of the humid north, debris-covered cirque glaciers with moraine dams occur in central catchments, and active talus rock glaciers dominate toward the arid south. **Figure 7** shows how process–form domains have shifted in space and time in response to a rise in ELAs since the Last Glacial Maximum, highlighting a shift along the spectrum from coupled to uncoupled landsystems due to reductions in ice-covered area and the importance of glacial transport and runoff.

Plateau Ice Field Landsystem

The plateau ice field landsystem concept has been applied by [Rea et al. \(1998\)](#) and [McDougall \(2001\)](#) to the reconstruction of Younger Dryas glacier cover in the English Lake District. Initial reconstruction by [Sissons \(1980\)](#) featured extended valley head glaciers that lay below large upland massifs, thereby necessitating the proposal for three separate snowfall intensity zones, in combination with the effects of snowblow and aspect, to account for considerable variations in glacier extent and ELAs (the latter varying by 500 m). Recent mapping of the glacial landforms has revealed that, similar to modern glacierized plateau terrains, the English Lake District valley heads contain substantial volumes of glacial sediment in latero-frontal and linear hummocky moraines that extend in many cases onto plateau margins. Evidence of plateau ice is patchy and often restricted to scoured bedrock at plateau edges. Sissons' 'valley' glaciers were therefore actually outlet lobes of a plateau ice field (**Figure 8**). [McDougall's \(2001\)](#) paleoglacier reconstructions for the English Lake District, incorporating plateau ice fields, suggest that ELAs during the Younger Dryas were up to 90 m higher than those calculated by Sissons based on an Alpine style of glaciations with no plateau ice.

Paleo-Ice Stream Landsystem

Evidence for a terrestrially terminating, rubber-stamped, paleo-ice stream has been identified by [Stokes and Clark \(2003\)](#) in the Dubawnt Lake area of the Northwest Territories of Canada (**Figure 9**). The ice stream formerly drained the northwestern portion of the Laurentide Ice Sheet and has been recognized by subglacial bedforms that conform to the patterns expected in zones of converging trunk and terminal diverging flow in a terrestrial ice stream. Additionally, the landsystem includes abrupt lateral margins and MSGs from which high ice flow velocity is inferred. The clarity of the ice stream bedform signature, with no discordances or crosscuts, qualified it as a rubber-stamped record of ice stream shutdown.

Conclusion

Paleoglaciological reconstructions, at scales ranging from local to continental, play a significant part in the development of models of global paleoclimate. However, the great spatial and temporal complexity of glacial processes and forms have necessitated the compilation of process–form models or landsystems that relate to various glaciation styles and systems, which may then be applied to specific physiographic and climatic settings. A number of contemporary glacierized landscapes have been employed as modern analogs for the

landform–sediment assemblages produced by different glaciation styles and ice dynamics in differing climatic, geologic, and topographic settings. The identification of modern landsystems (e.g., those pertaining to active temperate glacier snouts, glaciated valleys, plateau ice fields, and ice streams) provides glacial geomorphologists with the criteria to decipher paleoglacier dynamics and former glacier–climate relationships in ancient glaciated terrain.

Introduction

The vast amount of meltwater released from glaciers has enormous erosional capacity. Temporary impoundments of meltwater occur on top of, within, at the base of, and in front of the ice. The magnitude and intensity of erosion is greatest when these impoundments release sediment-deficient meltwater suddenly or rapidly in the form of outbursts. Erosion is facilitated by high hydraulic potential caused by the cryostatic pressure of the ice or the hydraulic head developed behind a barrier in a proglacial lake. The type and resistance of bed material underlying a region also controls the form and size of erosional landforms produced by these meltwater discharges.

Most glaciofluvial landforms of erosion were formed when the great Pleistocene ice sheets of North America and Eurasia produced and ponded vast quantities of meltwater. The erosional landforms include vast channel systems, both subglacial and proglacial, and a variety of forms attributed to subglacial sheetfloods. In some cases, subglacial flows switched from an erosional to a depositional regime upon reaching the glacier terminus, typified by aggrading braided streams, sandar, or subaqueous fans of various types.

The discharges that formed large-scale glaciofluvial erosional forms had significant global impacts because they were of such high magnitude. Many large-scale drainage systems in areas affected by glaciation were formed or largely modified by discrete event, high-discharge meltwater flows. In places, these channels constitute important aquifer systems, some of which are buried beneath multiple sheets of glacial drift from earlier glaciations. In addition, numerous studies have argued that the sudden release of vast quantities of cold meltwater correlates with periods of climatic change, possibly by altering oceanic circulation patterns.

Four categories of processes and landforms are considered in this article because they account for the majority of large-scale glaciofluvial erosional forms: (1) proglacial lake channel systems formed by glacial lake outbursts, (2) tunnel valleys formed by channelized subglacial flows, (3) ice-marginal (lateral) meltwater channels associated primarily with cold-based glaciers, and (4) a variety of erosional forms hypothesized to have been formed by subglacial sheet flows. This review of erosional landforms and related processes includes ideas that are universally accepted, such as a catastrophic flood origin of the Channeled Scabland in the United States, and a discussion of subglacial landforms attributed to fluvial erosion, which are actively debated and highly controversial.

Glacial Lake Outbursts

Overview

Glacial lake outbursts, or jökulhlaups, are very high-magnitude floods caused by the sudden drainage of water from a glacial

lake. Glacial lakes form on, in, under, or in front of glaciers and are inherently unstable. Outbursts occur in many present-day glaciated regions, such as Iceland, Alaska, the Himalayas, and the Andes ([Figure 1](#)). Flood discharges typically exceed background rates by orders of magnitude and, during the Pleistocene, carved out spectacular landscapes by flows of unparalleled magnitude. In fact, glacial lake outbursts account for the top seven floods ever known to have occurred in the world ([O'Connor and Costa, 2004](#)). Floodwaters from Pleistocene glacial lake outbursts were highly erosive and created a characteristic suite of landforms, now widely accepted to have formed by catastrophic floods. The geomorphic record of outbursts is most significant from Pleistocene glaciations because of the high magnitude of flows, in some cases exceeding $10 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ ([Baker et al., 1993](#); [Burr et al., 2009](#)). The emphasis here, therefore, is on Pleistocene glacial lake outburst erosional landforms, although valuable insights into outburst processes have been gained by observations of modern jökulhlaups ([Cenderelli and Wohl, 2003](#)).

Recognition of Pleistocene Glacial Lake Outbursts

For more than a century, the incongruity in size between underfit present-day streams and overfit valleys has been apparent. Furthermore, numerous studies suggested that the overfit valleys were paleochannels – not valleys, as evidenced by uniformity in size over long distances and regular meander wavelengths – that conveyed much higher discharges than present during the Pleistocene. Many of these same channels are now widely recognized to have formed by glacial lake outbursts. This acceptance was not the case when [Bretz \(1923\)](#) first proposed a catastrophic flood origin for the Channeled Scabland: an anastomosing network of channels, covering an area about 40000 km², in the Columbia Plateau of northwestern United States. Bretz, based on years of fieldwork, was compelled to argue for a catastrophic flood, the Spokane Flood, to explain the eroded basalt and loess landscape containing a network of proglacial channels, bedrock cataracts, streamlined islands, dry valleys, and boulder deposits ([Figure 2](#)). His hypothesis was widely rejected for some scientific reasons, including the lack of a known water source for the flood, but more importantly because the idea of a catastrophic origin to a landscape was viewed as an assault on the principle of uniformitarianism – the foundation of modern geology. In the 1960s, Bretz's outrageous hypothesis became widely accepted, now well supported by, among other things, a water source (Glacial Lake Missoula), giant current ripples, and high-altitude imagery ([Figure 3](#)). This fascinating story in the evolution of scientific ideas is well described (e.g., [Baker, 2009](#); [Baker et al., 1987](#)).

Today, dozens of investigations have shown that glacial lake outbursts were not unique to the Channeled Scabland; they were a common, if not inevitable, process during

Figure 3 Landsat image of Channel Scabland, Washington State, USA. Flood flows were from the northeast toward the southwest.

Pleistocene glaciations as the land, ice sheets, water sources, and drainage pathways were in a continuous state of flux. Along the margins of the Laurentide Ice Sheet, for example, three dozen outbursts have been documented (Figure 4; Kehew et al., 2009). Channel systems, mostly glacial lake spillways, have been attributed to glacial lake outbursts in Siberia, Iceland, and Scandinavia. Recent investigations of the Antarctic Ice Sheet show that vast amounts of subglacial meltwater exist. Some of this meltwater is highly dynamic and likely formed scabland-like topography beneath the ice sheet in the past (Denton and Sugden, 2005). Characteristic megaflood features also occur on the Martian landscape (Burr et al., 2009).

Glacial Lake Outburst Erosional Landforms

The Channeled Scabland is clearly the most studied area formed by outburst floods. Many landforms now used as indicators of catastrophic floods were first described in this region (Baker, 1973). Although the outburst flood origin of landforms of the Scablands is widely accepted, the number and timing of the outbursts, the magnitude and frequency relationships of the floods, the erosional capability of the outbursts, and the source of flood waters are actively studied (Baker, 2009; Benn and Evans, 2010). Spillway systems that formed by outbursts along the southern margins of the Laurentide Ice sheet, though not as dramatic as the Scabland landscapes, share many of the erosional landforms and have been well documented (Kehew and Lord, 1987). The most ubiquitous erosional landform created by outburst floods is a trench-shape channel with steep sides and a relatively uniform width and depth (Figure 5). The size of the channel varies with flow magnitude, geologic setting, and flow history among other things. Spillways that formed by outbursts in the Great Plains of North America are typically 1–3 km wide and 25–100 m deep (Kehew and Lord, 1987). Common erosional landform types produced by outbursts are summarized in Table 1.

General models for the sequence of development of flood-eroded landscapes have been developed on the basis of studies of the Channeled Scabland, outburst spillways in the Great Plains, and experimental flume studies (respectively, Baker et al., 1987; Carling et al., 2009; Kehew and Lord, 1987; Kehew et al., 2009; Shepard and Schumm, 1974; Wohl and Ikeda, 1997). Initial stages of flooding overwhelm the landscape and cause broad scouring, shallow anastomosing channels, and, in some cases, transverse erosional bedforms. With increased duration, the flow becomes more organized as the bed deforms, which is reflected in longitudinal grooves and streamlined hills. Continued flow leads to selective deepening to form inner channels, which progressively enlarge by capture of more flow laterally and by upstream knickpoint migration. A spillway formed by a long duration or repeated outbursts floods can convey all flow in one channel and may contain only a few very well streamlined hills (Figure 6).

Hydrologic Characteristics of Pleistocene Glacial Lake Outbursts

The cataclysmic failure of ice dams impounding large glacial lakes released huge volumes of water, over 2000 km³ in the Channeled Scabland, in a matter of days to weeks (O'Connor

Figure 4 Proglacial lakes and spillways along the southwestern margins of the Laurentide Ice Sheet. Reproduced from Kehew AE and Teller JT (1994) History of Late Glacial runoff along the southwestern margin of the Laurentide Ice Sheet. *Quaternary Science Reviews* 13: 861.

Figure 5 Oblique aerial photograph of inner channel and shallow, anastomosing channels on scoured uplands, Souris Spillway, southeastern Saskatchewan. Flow was to the east (top to bottom). Photography by Mark Lord.

and Baker, 1992). Outburst flows were highly erosive and, at least in much of the Great Plains spillway systems, became hyperconcentrated as they ripped through generally weak, fine-grained materials that underlie the region (Lord and Kehew, 1987). The sedimentary record of outburst floods is scarce in spillways, is present in some glacial lakes that received floodwaters (e.g., Lord, 1991), but is mostly present in the marine offshore record (e.g., Normark and Reid, 2003).

The largest well-documented outburst flood occurred in south-central Siberia in the Altay Mountains, which carved out gorges and produced megaripples in huge gravel bars analogous to those in the Channeled Scabland (Baker et al., 1993). Peak discharge is estimated to have been $18 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ with flows up to 500 m deep and velocities up to 45 m s^{-1} ; the unit stream power generated by this flood is estimated to have been 10^6 W m^{-2} . Paleohydrologic studies of lower magnitude outbursts typically estimate discharges to be between 10^4 and $10^6 \text{ m}^3 \text{ s}^{-1}$ (see Benn and Evans, 2010, for summary). The

Table 1 Erosional landforms produced by glacial lake outbursts

Landforms	Characteristics
Trench-shape channels (Figure 5)	Commonly parallel to ice margins and connect or bisect glacial lake beds
Anastomosing channel pattern	Network of channels may be from 1 to 100 km wide
Streamlined erosional residuals (islands) (Figure 6)	Erosional residuals, given long enough flow, will assume a lemniscate form that minimizes fluid drag
Dry valleys (channels)	Variable sizes, commonly on upland areas above deeper inner channels
Perched (hanging) channels	Variable sizes
Longitudinal grooves (Figure 5)	Flow parallel grooves interpreted to be formed by secondary circulation cells; up to 3 m high in Scablands and up to 2 m high in Great Plains
Cataracts (Figure 2)	Dry Falls in the Channeled Scabland is 5.5 km wide and 120 m high, probably formed by the coalescence of potholes eroded by vertical vortices (Baker et al., 1987)
Potholes and obstacle scour depressions	Occur at scales of meters to hundreds of meters
Transverse erosional ripples	Scarce landform present in well-preserved parts of Great Plains outburst flow paths (up to 1.2 m high with about 40 m wavelengths)
Erosional scarps	Commonly cut into terraces or valley sides

Compiled from **Baker (1973)**, **Baker et al. (1987)**, and **Kehew and Lord (1987)**.

Figure 6 Oblique aerial photograph of streamlined hill in the Souris-Hind spillway, southern Manitoba; flow was to the north (upper right to lower left). Photograph by Mark Lord.

specific characteristics of the erosional landscapes carved by these tremendous flows varied not just with discharge, but also with flow mechanics (e.g., flow regime, cavitation, secondary circulation), flow boundary materials, sediment availability, flow duration, flood hydrograph, and flow history (**Baker, 1973**; **Cenderelli and Wohl, 2003**; **Kehew and Lord, 1987**; **O'Connor and Baker, 1992**). For example, unit stream power has been used successfully to relate hydraulic conditions to different types of erosional processes and landforms.

Tunnel Valleys

Overview

Tunnel valleys, or tunnel channels (also known as tunneldale or rinnentaler), are large meltwater valleys eroded into sediment or rock at the base of an ice sheet. Valley dimensions reach >30 m deep, 4 km wide and more than 100 km long. Tunnel valleys have a wide variety of morphologies and associated landforms, and occur in drainage systems covering extensive areas.

The widespread distribution of tunnel valleys in the area of the Laurentide and Scandinavian Ice Sheets has important implications for ice-sheet dynamics and glacial meltwater regimes (**Brennand and Shaw, 1994**; **Clayton et al., 1999**; **Jørgensen and Sandersen, 2006**; **Mooers, 1989**; **Wright, 1973**). Although literature on tunnel valleys is abundant, controversy exists surrounding the mechanism of tunnel-valley genesis and the implications of meltwater volumes associated with the sizes of some of the valleys. As yet no unified theory on their formation can adequately explain the observed diverse morphologies, landform associations, and substrate lithologies (**O'Cofaigh, 1996**).

The terms 'tunnel valley' and 'tunnel channel' have often been used interchangeably to denote subglacially eroded drainage courses. However, these terms may also have genetic implications (**Clayton et al., 1999**; **Mooers, 1989**). For example, **Clayton et al. (1999)** use the term 'tunnel channel' to refer to erosion during a single or small number of events in which the flow depths and widths are comparable to the size of the valley. The magnitude of discharge inherent in this type of event is usually implied to be short-lived and catastrophic in nature. In this discussion, the term tunnel valley is used to describe landforms eroded by subglacial meltwater without a specific genetic origin.

Morphology

Despite a general orientation subparallel to longitudinal flow lines of the glacier, tunnel-valley drainage patterns are highly variable, including isolated straight valleys, braided and dendritic networks, radial, subparallel valleys (**Figure 7**) and anastomosing and anabranching systems (**Figure 8**) (**Brennand and Shaw, 1994**; **Clayton et al., 1999**; **Mooers, 1989**; **Sjogren et al., 2002**; **Wright, 1973**).

Valley morphologies are equally diverse and include straight-walled channels of uniform width (**Figure 9**), crenulated valleys that expand and contract, and subtle valleys only recognizable as linear chains of lakes or depressions. Buried tunnel valleys with no surface expression occur in the North Sea, Denmark, and the southern margins of the Scandinavian Ice Sheet (**Huuse and Lykke-Andersen, 2000**; **Jørgensen and Sandersen, 2006**). Many tunnel valleys display steep walls similar to outburst spillways, but others display irregular widths and depths and variable degrees of posterosional infill. Longitudinal profiles of flow paths may be undulating and have convex-up or reverse gradients that flow uphill, cross drainage divides, and trend oblique to the regional slope (**Figure 10**) (**Clayton et al., 1999**; **Kozłowski et al., 2005**; **Wright, 1973**). In other areas, tunnel valleys occur as isolated,

hanging, channel sections adorning uplands without integration to other channels or modern drainage.

Valley dimensions range from 0.15 to 6 km in width and 2–150 km in length, but the majority of valleys are 0.5–2.5 km wide and 5–40 km long. Valley depths of 10–50 m are common, with most ranging between 20 and 30 m, although subsurface studies of deeply buried tunnel channels document depths in excess of 100 m (Piotrowski, 1994). Other subsurface investigations have indicated that the subtle surface expression of some valleys is attributable to burial or partial burial by thick sequences of younger sediment that obscures the true depth of the valley bottoms (Clayton et al., 1999). Despite a general lack of adequate subsurface information and a scarcity of exposures, available studies suggest that a wide range of sedimentary sequences fills or partially fills tunnel valleys (Benn and Evans, 2010; Brennand and Shaw, 1994; Piotrowski, 1994).

Landform Associations

Tunnel valleys are often closely associated with drumlins, eskers, moraines, glaciofluvial meltwater fans, and hummocky topography. Several studies have noted that tunnel valleys cross-cut drumlins (Brennand and Shaw, 1994), contain eskers (Kehew and Kozłowski, 2007), and end at past ice-marginal positions (Clayton et al., 1999; Cutler et al., 2002), where they cut through the terminal moraine at the apex of large, coarse-grained glaciofluvial fans (Figures 11 and 12). Where active ice margins were in close proximity but not necessarily in synchronicity, some tunnel channels display cross-cutting relationships with younger landforms and have been interpreted as palimpsest tunnel channels (Kehew et al., 1999). These

cross-cutting relationships may be used to establish or constrain relative timing of glacial events in complex glaciated regions where the chronology of events is poorly constrained (Kehew et al., 1999; Kozłowski et al., 2005).

Although widely varying in morphology, drainage pattern, and associated landforms, there is a general consensus that tunnel valleys

- are subparallel to glacial flow lines, drumlins, and eskers;
- are usually straight and lack tributaries except for postglacial gullies;
- are most distinct near ice margins;
- have undulatory longitudinal profiles with uphill reaches;
- commonly contain eskers; and
- often breach moraines and terminate at large, coarse-grained glaciofluvial fans.

Origin

Most of the controversy surrounding tunnel channels centers on the models proposed to explain their formation (O’Cofaigh, 1996) and relationships with various landform associations (Benn and Evans, 2010). There is a fundamental difference in interpretation between those who use the term ‘tunnel channel’ to represent bankfull meltwater flow during one or more discharge events (Clayton et al., 1999) and those who use the term ‘tunnel valley,’ which implies gradual erosion by flows much smaller than the dimensions of the valley (Boulton and Hindmarsh, 1987; Mooers, 1989).

Although multiple models of formation have been proposed, most fall into four categories: (1) catastrophic meltwater floods, (2) time-transgressive erosion, (3) subglacial

Figure 10 Digital elevation model of south-central Michigan displaying a series of anastomosing Saginaw Lobe tunnel channels (red lines) with segments that flowed uphill and crossed drainage divides (dashed white lines on DEM and inset profiles) to feed a subaerial outburst flood in the Central Kalamazoo River Valley. sediment deformation and piping, and (4) polygenetic origin (Figure 13). Catastrophic meltwater release is the most commonly suggested mechanism for tunnel channel formation and, although differences in opinion exist over the exact nature

of the flow regime, most authors argue for large-scale transient events. The model shown in Figure 14 illustrates that after erosion by a large discharge, ice will flow under pressure into the valley. Smaller discharges confined to a restricted area of the former channel then form eskers over longer time periods. Several researchers have suggested that formation of tunnel channels is largely controlled by glacier-bed conditions and the presence of a permafrost seal at the glacier margin (Clayton et al., 1999; Wright, 1973). Hooke and Jennings (2006) have developed a model for channel erosion, which begins by discharge of pressurized groundwater at or near the margin. High fluid-pressure gradients lead to erosion of soil particles, a process called piping, and headward extension of the channel. When the channel reaches a reservoir of subglacial meltwater behind the permafrost wedge, it catastrophically drains to the margin (Figure 15). The source of meltwater remains a contentious issue and significant subglacial reservoirs of meltwater are required for rapid erosion of channels of the scale of those observed.

Alternatively, Mooers (1989) suggested that formation of large erosional troughs in Minnesota resulted from

Figure 12 Digital elevation model of a Saginaw Lobe tunnel channel fan in south-central Michigan, USA. Note channel ascends in elevation to the apex of the fan, which is the highest feature on the landscape and delineates a former ice margin. Also, the collapsed appearance of the channel extending through the medial and distal portions of the fan suggests the channel extended beyond this margin and had been occupied prior to burial.

time-transgressive discharge of seasonal supraglacial meltwater that accessed the subglacial system via crevasses and moulins. Valley formation, as opposed to channel formation, resulted incrementally from vertical and lateral planation of subglacial meltwater streams (**Figure 13(b)**). This model accounts for the association of eskers and meltwater fans sometimes observed with tunnel channels, does not require catastrophic flows, and does not require permafrost to act as a hydraulic seal. In this model, small subglacial discharges gradually eroded the observed valleys as the ice margin retreated.

Subglacial deformation in conjunction with groundwater sapping, is another formational model that has been suggested for the development of tunnel valleys (Boulton and Hindmarsh, 1987). In this model, basal meltwater is unable to infiltrate downward through deforming subglacial sediment because of the low transmissivity of the deforming beds. Lateral groundwater flow toward low-pressure tunnels is initiated in the substrate to sustain meltwater discharge and maintain glacier equilibrium. Because of the high fluid-pressure gradients, sediment deforms into the meltwater conduit by creep or piping and is entrained and transported down glacier, initiating or enlarging the tunnel (**Figure 13(c)**). In time, this process leads to a gradual formation of a valley much larger than the hydraulic conduit.

Figure 13 Schematic diagram illustrating proposed models of tunnel channel formation. (a) Catastrophic meltwater floods, (b) time-transgressive erosion, (c) subglacial deformation, and (d) hydraulic sapping or piping and collapse. Modified from Clayton L, Attig JW, and Mickelson DM (1999) Tunnel channels formed in Wisconsin during the last glaciation. In: Mickelson DM and Attig JW (eds.) *Glacial Processes Past and Present*, pp. 69–82, Special Paper 337. Boulder, CO: Geological Society of America.

The diversity in tunnel-valley morphology, drainage patterns, and substrate suggests a polygenetic origin for some valleys, which may involve preglacial, subglacial, glacial, and subaerial erosion (Benn and Evans, 2010; Brennand and Shaw, 1994; Clayton et al., 1999; Jørgensen, and Sandersen, 2006; O’Cofaigh, 1996; Sjogren et al., 2002). Once formed, tunnel valleys may be reoccupied during multiple glacial advances or glaciations (Benn and Evans, 2010). Buried and open tunnel valleys in northwestern Europe date from the Elsterian, Saalian, and Weichselian glaciations (**Figure 16**). The larger valleys are more than 100 m deep and completely buried. Huuse and Lykke-Andersen (2000) suggest that the origin of these large valleys involves a combination of repeated cycles of erosion and downcutting by catastrophic events, separated by steady-state subglacial meltwater flow and glacial erosion when closure by ice creep occurs. Deposition of a variety of sediment types occurs during interglacial periods.

Ice-Marginal (Lateral) Meltwater Channels

Overview

Channels eroded along or adjacent to former ice margins are referred to as lateral meltwater channels. These channels often occur in parallel, inset sequences, delimiting the gradual retreat

Figure 14 Conceptual model of tunnel-valley formation by high-discharge subglacial meltwater flows (a), partial closure of the valley by ice creep and drainage of lower-discharge flows through a smaller conduit during ice wastage (b), and final melting of glacier leaving an esker in a tunnel valley (c).

Figure 15 Formation of a subglacial lake behind a permafrost wedge. Groundwater under pressure from the ice overburden would drain toward the margin and break through the permafrost, initiating a conduit by piping. The conduit would extend headward to the lake and drain it catastrophically to form a tunnel channel. Reproduced from Hooke R LeB and Jennings CE (2006) On the formation of the tunnel channels of the southern Laurentide ice sheet. *Quaternary Science Reviews* 25: 1364–1372.

of a former glacier. Although not completely restricted to cold-based glaciers, lateral meltwater channels are best developed where glaciers are frozen to their beds.

Occurrence and Origin

Cold-based glaciers are most common in polar regions such as the Canadian Arctic Islands. Dyke (1993) mapped the landforms on several islands that supported ice caps during the last glaciation. These ice caps are now thought to be part of the Innuitian Ice Sheet (Dyke et al., 2002), which was confluent with the Greenland and Laurentide Ice Sheets. The thermal regime of these glaciers at the time of their maximum extents consisted of cold-based interiors and warm-based marginal areas. During deglaciation, they became entirely cold-based. Because cold-based glaciers have minimal subglacial meltwater, melting and meltwater production is confined to the ice surface. During the ablation season, meltwater from the ice and adjacent areas (if the topography slopes toward the glacier) drains toward the ice margin and then along the margin in the direction of the land slope. Channels are eroded by this meltwater flow. As the ice margin retreats, new channels replace those from the last period of meltwater flow, perhaps even forming on an annual basis (Dyke, 1993). In this way, a series of meltwater channels develops as the ice retreats (Figure 17).

As the result of the very minor amount of subglacial erosion and deposition performed by cold-based glaciers, lateral meltwater channels represent the most significant landforms produced by these ice masses. The closely spaced, parallel orientation of the channels suggests frequent abandonment in favor of new ice-marginal channels during orderly ice margin retreat, and the channels are therefore useful in mapping and defining the pattern of glacial retreat.

Although most common in cold-based glaciers, lateral meltwater channels may also form adjacent to temperate glaciers (Figure 18). Dyke (1993) attributes these occurrences to deflection of surface water to the margin by high subglacial meltwater fluid pressures or to intermittently or permanently frozen basal conditions during ice retreat.

Subglacial Sheetfloods – The Meltwater Hypothesis

Overview

Erosion of glacial substrates by subglacial sheetfloods, also known as the meltwater hypothesis, provides an alternative explanation for the formation of many glacial landforms that are traditionally interpreted as the result of direct action of glaciers upon their beds. A historical summary of the meltwater hypothesis (Shaw, 2002) reviews the major points of the hypothesis and includes a comprehensive citation of the literature.

Bedrock Erosional Forms

Glacier beds composed of hard bedrock exhibit a wide variety of erosional marks and forms. Some, such as striations, clearly formed by glacial abrasion. Other exposures, in which the bedrock surface is shaped into an assemblage of smoothed, streamlined forms, are more difficult to interpret. The name

Figure 16 Location and relative age of on-shore and off-shore tunnel valleys in northwestern Europe. Valleys are linked to the Elsterian, Saalian, and Weichselian glaciations. 'P form' (plastically molded) has been applied to these features, with the interpretation that they were produced primarily by the action of plastically deforming ice. Kor et al. (1991) concluded that these forms were instead the product of a turbulent, viscous fluid – sediment-rich subglacial meltwater – and suggested the generic term 'S form' (sculpted) for them. In their study area on the northeastern side of Georgian Bay, Lake Huron, the forms range in size from centimeters to tens of meters. Their classification of the forms is shown in Figure 19. Formation by meltwater rather than plastically deforming ice, or till, is based on form analogy to marks produced by experimental erosion of cohesive or hard substrates by turbulent fluid flows. The process envisioned for the formation of S

forms by meltwater involves the action of vortices and other flow structures impinging on an irregular bed (Kor et al., 1991). One of these flow structures, the horseshoe vortex (Shaw, 1994), is illustrated in Figure 20, and an exposure of sculpted bedrock on Kelley's Island, Lake Erie, is shown in Figure 20. The Georgian Bay flood was estimated by Kor et al. (1991) to have been 70 km wide and 10 m deep, with a velocity of $5\text{--}10\text{ m s}^{-1}$, producing a discharge of $0.4\text{--}0.7 \times 10^7\text{ m}^3\text{ s}^{-1}$.

Pair (1997), in a study of bedrock erosional forms in northern New York, reached the conclusion that, although many of the forms were indicative of meltwater erosion, they were limited to bedrock valleys in which channelized subglacial drainage would have been concentrated. Pair also points out

that plastic deformation of basal ice over an irregular bedrock surface would prevent the kind of broad decoupling of the ice from its bed required by the meltwater hypothesis (Figure 21).

Drumlins, Rogens, Hummocky Terrain, Megaflutes, and Tunnel Valleys

Although the immense discharges required by the meltwater hypothesis attract continued criticism, there is general agreement that at least some of the S forms observed on bedrock surfaces were eroded by turbulent subglacial meltwater. The meltwater hypothesis encounters an even greater degree of controversy, however, in the explanation of drumlins, rogens, and hummocky terrain, landforms occurring in mostly unconsolidated materials, as the result of subglacial

megaflows rather than the traditional explanation of direct glacial action. This extension of the hypothesis was initially applied to the Livingstone Lake drumlin field in northern Saskatchewan. Form analogy of the drumlins to the inverted sole of a turbidite bed led to the inference that the drumlins formed by infilling of erosional marks scoured upward into the base of the ice sheet, perhaps during the waning phases of the flood (Shaw and Kvill, 1984). Shaw et al. (1989) estimated the total volume of water released as $84 \times 10^3 \text{ km}^3$.

The recognition of drumlins with truncated internal structure at land surface led to the broadening of the meltwater hypothesis to include drumlins formed by scour of the subglacial bed by the sheetflood rather than scour of the base of the ice (Shaw and Sharpe, 1987). Form analogy is also used here as a basis for the process, in this case to the large-scale, streamlined erosional hills of the Channeled Scabland and elsewhere. Interpretation of landforms other than drumlins by similar mechanisms was soon to follow. Rogen moraine was explained by infill of scours in basal ice oriented transverse to the flow direction of the sheet flow (Fisher and Shaw, 1992). Munro and Shaw (1997) added hummocky terrain to the hypothesis. This interpretation was based on landscapes in Alberta where hummocks, covered with boulder lags, have internal structures that are truncated at the land surface. The hummocky terrain occurs adjacent to incised 'flood tracts'; the hummocky terrain itself is attributed to less severe erosion on the flanks of the main channels or tracts. Tunnel valleys are usually explained by the collapse of the sheet flows that produce drumlins into channelized flows.

Spirited debate continues on the meltwater hypothesis (Evans et al., 2006). Form analogy as the most fundamental evidence for landforms produced by subglacial sheetfloods has been challenged on several grounds. In the case of cavity infill landforms, confirmation of process by form analogy requires extrapolation over orders of magnitude; in addition, Benn and Evans (2010) have pointed out that dissimilar processes can produce similar landforms. The formation of drumlins, rogen

Figure 18 Lateral meltwater channels (LMC) and spillways near Syracuse, NY, USA. Lateral channels developed as meltwater from the Ontario Lobe of the Laurentide Ice Sheet grounded against the Onondaga Escarpment. Meltwater discharges trapped between the ice margin and uplands scoured channels (outlined and arrows) down to bedrock. Some of the deep north-south valleys carved into the escarpment contained proglacial lakes. Spillways (SP) were incised as ice retreated northward and lower outlets opened.

moraine, and megaflutes by bed deformation by glacial ice is well established in the literature, although details continue to be controversial. Other problematical aspects of the meltwater hypothesis include the lack of erosional landforms beyond the ice margins from which megafloods emerged and the lack of

evidence for the huge meltwater reservoirs necessary for the generation of megafloods. Clarke et al. (2005) contend that both the production of sufficient meltwater and its storage on top of or beneath ice sheets are unlikely without special circumstances.

Glacitectonic Structures and Landforms

D J A Evans, Durham University, Durham, UK

© 2013 Elsevier B.V. All rights reserved.

Glacitectonic Processes

Proglacial glacitectonics involves the large-scale displacement of proglacial materials due to stresses imposed by glacier ice and involves ductile or brittle deformation or a combination of the two. Ductile deformation involves the production of large, open folds in sediments or rocks in front of an advancing glacier, which may develop into overfolds or begin to undergo internal thrusting due to continued ice advance. In contrast, brittle deformation involves the thrusting of semicoherent blocks along discrete planes of failure. In both cases, the lower limit of deformation is usually marked by a basal failure plane or plane of decollement, which often coincides with a sedimentary discontinuity or bedding plane. Although all materials are capable of undergoing both ductile and brittle failure according to variations in the applied stress, temperature, strain rate, and porewater pressure, glacitectonic disruption of frozen sediments appears to be dominated by brittle failure (e.g., Evans and England, 1991; Kalin, 1971; Klassen, 1982).

The compression of proglacial materials by glacitectonic deformation is very similar to the processes that occur during continental collision and mountain building (Aber, 1988; Croot, 1987). Indeed, proglacial glacitectonic landforms can be regarded as scale models of mountain chains and can be studied using well-founded principles of structural geology (see Twiss and Moores, 1992; Figure 1). The formation of large thrust–moraine complexes standing many tens of meters above the surrounding terrain depends on a number of factors, the most important of which are low-strength proglacial sediments and high, glacially imposed stresses. Sediment strength is dependent upon grain size and sorting, the existence of potential planes of failure, and porewater pressures. High porewater pressures result from subglacial drainage through inefficient distributed systems, such as porewater flow, and can be further encouraged by the existence of proglacial permafrost, which acts to confine pressurized porewater in underlying unfrozen aquifers (Mathews and Mackay, 1960).

The presence of weakened sediments, however, is not a sufficient condition for proglacial glacitectonic deformation, which also requires stresses large enough to elevate large masses of sediment above the glacier margin. It is clear that in most situations, the shear stresses beneath glacier margins are too low to produce the observed deformation. The solution to this problem was developed by Rotnicki (1976), van der Wateren (1985), and Aber et al. (1989), and is known as the ‘gravity spreading model.’ According to this model, proglacial sediment failure results from the translation of the weight of the glacier into lateral stresses, which push sediment wedges away from the load and then upward from their original position. The stress field producing a thrust block is therefore the product of the total weight of the ice mass and older thrust blocks. Williams et al. (2001) have demonstrated this concept on the St Bees Moraine in northwest England by applying a

critical wedge model developed in structural geology. In addition to gravity spreading, two other mechanisms may contribute to the development of thrust systems (Aber et al., 1989; Price and Cosgrove, 1990). First, gravity gliding or gravity sliding involves the deformation of sediment blocks as they move downslope under their own weight. This requires the uplifting of the ice proximal zone by gravity spreading to produce a slope upon which blocks can slide. Second, compression or push from behind may occur by the direct shoving of sediment wedges by the forward movement of the glacier. In reality, gravity spreading, gravity gliding, and compression can act in unison in proglacial settings.

The likelihood of glacitectonic disturbance is dictated by various factors (Aber et al., 1989), the most important of which are (i) slope of the proglacial area, whereby ice advance against a topographic obstacle increases the likelihood of proglacial glacitectonics; (ii) the presence of weak layers in the substratum, whereby failure is encouraged by weak layers or potential decollement planes; (iii) the nature of ice/sediment contact in the proglacial area, where partial burial of glacier snouts prior to their advance may lead to the lifting of sedimentary strata; and (iv) subglacial and proglacial drainage, whereby failure is encouraged by high porewater pressures in proglacial and submarginal sediments and rocks.

The shortening of proglacial sediments and rocks during glacitectonic deformation results in complex geological structures analogous in many ways to thrust-fold belts at the collision points of drifting continents, and can be explained using the principles of structural geology (Figure 2). Ductile deformation during glacitectonic compression and shortening results in a wide range of fold types, depending on the magnitude and orientation of the applied stresses and the strain response of the sediments. Folds range from long wavelength or open folds to isoclinal or recumbent (nappe) folds. Other fold types include chevron, sheath, kink band, box, and polyclinal folds. Complexities may arise where different sedimentary layers respond differently to stress and produce disharmonic folds, in which the fold wavelengths of some layers are smaller than those of others. Additionally, the response of water in Quaternary sediments when put under pressure results in a range of small-scale soft sediment deformation structures, hydrofracture fills, and burstout structures (Phillips et al., 2007; Rijdsdijk et al., 1999). Complex deformation histories can be evident in the superimposition of folds on preexisting structures (Berthelsen, 1978), allowing the reconstruction of glacier marginal oscillations (e.g., Phillips et al., 2002). Syntectonic sedimentation can also contribute to significant complexity in Quaternary glacial stratigraphies, an excellent example being that of the tills, glacitectonites, and associated sediments of the Norfolk coast in Britain, where proglacial tectonics led to the construction of thrust ridges and intervening depressions that acted as ‘foreland’ basins for localized sedimentation (Phillips et al., 2008; Figure 3).

Figure 1 Example of the tectonic structures produced by the thrusting of stratified sand in a squeeze box. These features are typical of moraines constructed by proglacial glacitectonics: (1) initiation of thrust, (2) thrust fault, (3) slump zone, (4) extension fractures, (5) back kink fold, and (6) backthrust zone. Reproduced from Mulugeta G and Koyi H (1987) Three-dimensional geometry and kinematics of experimental piggyback thrusting. *Geology* 15: 1052–1056.

Composite Ridges and Thrust-Block Moraines

The most common and distinctive type of glacitectonic landforms are composite ridges and thrust-block moraines (Figure 4(a)). Composite ridges are composed of multiple slices of upthrust and contorted bedrock and/or unconsolidated sediments, which are commonly interlayered with and overlain by glaciogenic and glaciofluvial sediment (Aber et al., 1989). They are subdivided by Aber et al. (1989) into large (>100 m of relief) and small (<100 m of relief) composite ridges. This size differentiation is essentially arbitrary and the processes involved in the production of both large and small composite ridges are the same. However, Aber et al. (1989) suggested that large ridges usually contain a considerable volume of pre-Quaternary bedrock, whereas small ridges are composed mostly of unconsolidated Quaternary strata. The term thrust-block moraine was introduced by Evans and England (1991) to describe composite ridges comprising proglacially thrust masses of permafrozen blocks of Quaternary sediments at the margins of Arctic subpolar glaciers. Composite ridges are associated with proglacial or submarginal glacitectonics and they mark the positions of glacier stillstands or readvances.

In planform, composite ridges comprise arcuate suites of subparallel ridges and intervening depressions arranged in a concave up-glacier pattern and conforming to the general shape of the glacier margin that produced them. Individual

ridge crests correspond to the crests of internal folds, the upturned ends or edges of thrust blocks, or resistant upturned beds. The depth of disturbance associated with composite ridges is generally a few tens of meters and may be up to 200 m for the very largest features (Aber et al., 1989; Kupsch, 1962). The internal structures of large composite ridges are very similar to the products of thin-skinned tectonics in thrust and folded mountain belts like the Canadian Rockies, even though composite ridges are at least one order of magnitude smaller than true mountain ranges (Aber et al., 1989). The material in composite ridges commonly forms stacked sheets, with individual thrust slices showing varying degrees of internal deformation. Overturned and rootless folds of bedrock and Quaternary sediments in the composite ridges at Flade Klint, Denmark, have been thrust up to 100 m from their probable source depression (Gry, 1940). Probably, the most spectacular exposures through a large composite ridge are located at Møns Klint in Denmark. Several ice advances during the last glaciation have piled up numerous chalk scales with intervening Quaternary sediment to produce a composite ridge characterized by more than 150 m of structural relief (Aber, 1985). The structures within the cliffs at Møns Klint include multiple thrust anticlines and individually folded and stacked chalk floes, which can be traced as a series of ridges on the rugged highland of Høje Møn.

There are numerous examples of small composite ridges, both in front of modern glacier snouts and in the ancient

Figure 2 Glacitectonic structures and landforms associated with proglacial thrusting by the snout of Holmstrombreen, Svalbard: (a) block diagram of the thrust and folded sediments that constitute the moraine at the glacier snout; (b) styles of glacitectonic disturbance that can be observed at Holmstrombreen; A = undeformed foreland; B = 'Jura-style' high-angle folding; C = low-angle structures including thrusts and overturned and recumbent folds; D = nappes; E = deformed subglacial sediment/tills where Ec is compressive and Ee is extensional. Reproduced from [van der Wateren DFM \(1995\)](#) Processes of glaciotectionism. landform record. Spectacular composite ridges composed of outwash and glacial marine sediments form continuous moraines around the snouts of many Spitsbergen glaciers ([Croot, 1988](#); [Gripp, 1929](#); [Gripp and Todtmann, 1925](#)). In Spitsbergen and Iceland, composite ridges are strongly associated with surging glaciers, suggesting that conditions during surges are particularly conducive to proglacial tectonics ([Croot, 1987, 1988](#); [Evans and Rea, 2003](#); [Sharp, 1985](#)). The most important factors underlying this association are (i) rapid advance of the snout, (ii) extreme compressive deformation at the margin, and (iii) elevated pore-water pressures associated with the release of meltwater. The role of porewater pressures is highlighted by the general absence of composite ridges where proglacial areas slope steeply away from the glacier and water is able to drain away freely. The internal structures of recent composite ridges at Eyjabakkajökull, an Icelandic surging glacier, include low-angle subglacial thrust faults dipping down glacier, over which thrust slices have been transported during overall extension, and proglacial compression structures, such as stacked thrust sheets composed of outwash, tephra, turf, organic soil, and peat beds, which form asymmetric ridges. In the more distal parts of the moraine,

smaller asymmetric ridges are the surface expression of anticlines or overturned anticlines ([Croot, 1988](#)).

Thrust-block moraines produced by proglacial thrusting of blocks of frozen outwash and raised marine sediments have been documented in the Canadian arctic ([Evans, 1989](#); [Evans and England, 1991](#); [Kalin, 1971](#); [Klassen, 1982](#); [Figure 5](#)). In most examples, the bedding within individual blocks and block surfaces dip gently toward the glacier, suggesting that the moraines are composed of either stacked scales or partially rotated deep-seated blocks ([Kalin, 1971](#)). In some cases, however, bedding may dip away from the glacier snout suggesting deep-seated wedging of the advancing snout beneath proglacial sediments ([Evans and England, 1991](#)). The Canadian Arctic thrust-block moraines occur in areas where permafrost is often in excess of 700 m thick, but they are located in valley bottoms either below the marine limit or below former proglacial lake shorelines relating to the last glaciation. This suggests that permafrost may have been partially degraded below deep-water bodies prior to the Holocene advances responsible for thrusting. Therefore, block failure could have been initiated along an unfrozen talik between newly aggraded postglacial

Figure 3 The evolution of complexly deformed ice sheet marginal sediments due to deformation of proglacial outwash, based on the Quaternary deposits of north Norfolk, England. This idealized reconstruction of the processes and products of progressive proglacial to subglacial deformation is based upon the features observed at the cliffs between West Runton and Sheringham. surface permafrost and the degraded top of the full glacial permafrost. Thrust-block moraines at the margins of cold-based glaciers in the Dry Valleys area, Antarctica, are interpreted by Fitzsimons (1996) as the product of thrusting by cold-based glaciers overriding weak, unfrozen lake floor sediments. Unfrozen areas occur below either saline lakes or wet-based lakes which have a permanent ice cover but do not undergo full-depth freezing. As the glacier enters the lake, sediment blocks become frozen onto the base of the glacier, but can be thrust forward because their deeper layers remain unfrozen. In summary, therefore, the formation of thrust-block moraines in permafrost regions is thought to occur only within areas where unfrozen or only partially frozen sediments occur.

Hill-Hole Pairs

A hill-hole pair is defined as “a discrete hill of ice-thrust material, often slightly crumpled, situated a short distance down-glacier from a depression of similar size and shape” (Bluemler and Clayton, 1984; Figure 4(b)). Ice-thrust hills may be found at distances of up to 5 km from source depressions, but are usually closer (Bluemler and Clayton, 1984; Figure 6). However, source depressions can become infilled with younger sediment and are not always visible as surface features. Conversely, glacitectonic depressions are sometimes found without associated hills (Andriashek and Fenton, 1989), perhaps because positive relief features have been destroyed by subglacial erosion.

The typical morphology of a hill-hole pair is as follows (Aber et al., 1989): (i) the hill has an arcuate or crescentic planform, which is concave up-glacier; (ii) the surface of the hill is traversed by a series of transverse, subparallel ridges and depressions; (iii) the hill has an asymmetric cross-profile, with the highest point and steeper slopes on the convex or down-glacier side; and (iv) the topographic depression is approximately the same shape and area as the hill, located on the concave or up-glacier side. These morphologic features may be less obvious where prolonged subglacial modification has taken place after formation. The largest hill-hole pair so

Figure 5 Thrust-block moraine at the margin of a subpolar glacier in the Canadian high Arctic.

far recognized on the Earth's surface is Herschel Island in Mackenzie Bay, Canada, with an area of more than 100 km² (Mackay, 1959; Rampton, 1982) and composed of preglacial Pleistocene sediments thrust up from a now submerged source depression. Its internal structures include low-angle thrust faults, synclines, and anticlines, tilted beds which occasionally approach subvertical angles, overturned folds, repeated strata, slickensides, and segregated ice lenses which originally formed horizontally but now parallel the deformed enclosing strata (Mackay, 1959; Mackay et al., 1972).

Cupola Hills

Cupola hill is the English translation of the Danish term *kupelbakke*, which was introduced by Smed (1962) to describe irregular hills with the general characteristics of glacitectonic landforms but lacking hill-hole pair relationship and/or the transverse ridged morphology of composite ridges (Figure 4). The characteristics of cupola hills can be summarized as (i) they have a dome-like morphology varying from near circular to oval shapes with lengths of 1–15 km and heights of

Figure 6 Bittern Lake, AB, Canada, an example of a hill-hole pair. The glaciotectionally disturbed Cretaceous bedrock that comprises the ice-thrust hill is visible in the road cut.

20–100 m; (ii) internally, they are composed of detached and deformed floes of Quaternary sediments, older strata, or bedrock; and (iii) they have a carapace of till which truncates the underlying structures. These characteristics indicate that cupola hills are subglacially overridden hill-hole pairs or composite ridges and represent early stages in the development of drumlins or megafloodings. In cases where the subglacial modification has been slight, transverse ridge morphology may be partially preserved and the cupola form will tend to lie transverse to former ice flow. With increasing subglacial modification, ridge forms tend to be replaced by more smoothed, elongated forms. Viewed from the air, cupola hills may appear aligned in arcuate or transverse belts which conform to the former margins of glaciers. Where such belts occur, they represent the positions of former large composite ridges that have been modified by subglacial molding.

Examples of cupola hills composed entirely of Quaternary sediments include the island of Ven in Sweden and Ristinge Klint in Denmark (Aber et al., 1989). The island of Ven is composed of gentle synclines disturbed by numerous thrust faults and overturned folds. The glaciotectional disturbance responsible for these structures has produced two major transverse ridges, the surface of which is muted by a cover of discordant till. In contrast, the topography of Ristinge Klint is subdued and drumlinized similar to cupola hills on the nearby island of Aero (Smed, 1962). Cliff sections reveal that the area of Ristinge is underlain by more than 30 stacked scales of Quaternary sediments, each scale being up to 20 m thick and containing the same stratigraphic sequence of Saalian, Eemian, and Weichselian strata (Sjorring, 1983). The internal stratification of each scale is little disturbed except for prominent drag folds associated with the thrust faults between scales. Thrusting of the scales is thought to have occurred at the ice margin during glacier advance and deposition of the upper, discordant tills; surface streamlining took place during subsequent ice overriding. Other excellent examples of cupola hills occur in the late Wisconsinan end moraine systems that make up the offshore islands of New England, USA. The islands consist of glaciotectionally disturbed floes or thrust scales of Cretaceous, Tertiary, and Quaternary strata (Oldale and O'Hara, 1984).

Sections at Gay Head Cliff, Martha's Vineyard expose a series of layered scales, each 20–30 m thick and dipping up-glacier, interrupted by overturned folds, low-angle thrust faults, and occasional down-dropped blocks or grabens. In places, the strata have been uplifted by over 160 m.

Megablocks and Rafts

Megablocks and rafts are dislocated slabs of rock and unconsolidated strata which have been transported from their original position by glacier action (Ruszczynska-Szenajch, 1987; Sauer, 1978; Stalker, 1973, 1976; Figure 4(d)). Traditionally, such rafts were assumed to have been frozen on to the base of cold-based ice sheets, although it is now recognized that failure may occur along a basal decollement in a subglacial deforming layer. Megablocks may originate from uprooted cupola hills, although it is often difficult if not impossible to demonstrate detachment from the parent substrate unless there is exceptionally good exposure. Where they are subhorizontal, megablocks and rafts may form flat-topped buttes or plateaus and can be mistaken for bedrock outliers. Similarly, buried megablocks can be mistaken for bedrock if borehole logs or exposures are not available. Although megablocks and rafts contain coherent masses of bedrock or sediment, they are also commonly traversed by shear zones, faults, and brecciated zones, and may be folded.

Rafts of Jurassic clay more than 20 m thick at Lukow, Poland, are derived from Lithuania, more than 300 km to the northeast, and are thought to have been transported in a frozen state (Ruszczynska-Szenajch, 1987). A similar transport distance has been calculated for the Cooking Lake megablock near Edmonton, AB, Canada, which is 10 m thick and covers an area of approximately 10 km² (Stalker, 1976). A good example of the subsurface expression of a megablock occurs in the vicinity of the Qu'Appelle Valley, Saskatchewan. This block of Cretaceous shale is approximately 1000 km² in area with a maximum thickness of 100 m, and was discovered by borehole logging and bedrock contour mapping (e.g., Sauer, 1978). A well drilled at the western end of the megablock penetrated 80 m of brecciated and deformed bedrock of the Riding Mountain Formation and then 2 m of till. Steeply dipping rafts are more likely to have some surface expression, although they may be buried and difficult to identify without extensive borehole data. A series of detached chalk rafts occur in till overlying limestone in quarry exposures at Kvarnby in Sweden, suggesting that they were removed from the Baltic Sea bed and transported more than 25 km before being stacked at angles of up to 80° (Ringberg, 1983). These subsurface rafts lie beneath a structurally controlled, low-amplitude hummocky topography which would be difficult to differentiate from a cupola hill without exposures. Similarly, chalk rafts in the Anglian till of

Hertfordshire, England, have been identified in borehole records and as pale-toned patches in darker, freshly seeded fields on aerial photographs (Hopson, 1995). Unlike the Swedish examples, the Hertfordshire chalk rafts have been displaced only a short distance (mostly <1 km) from their origin by the southerly flowing Anglian ice sheet.

Introduction

Forms of glacial erosion are both the most obvious of landforms, recognized after a few classes in school, and yet the most difficult to fully explain and to date (Glasser and Bennett, 2004). Medium-sized glacial landforms, such as roches moutonnées, whalebacks, and rock drumlins are discussed in another article in this encyclopedia. Most of these are decametric and hectometric in scale but some, such as giant roches moutonnées, are kilometric. Here, we deal with the largest forms: cirques, troughs, rock basins, fjords, and landscapes of glacial erosion. These are on kilometric and larger scales; the smallest glacial cirques are on the order of 200 m in length and breadth.

Cirques show the former presence of cirque glaciers or the source areas of valley glaciers. Where ice from several cirques converged, forming a valley glacier, a trough was generally eroded. Further glacier growth in areas of high relief produced systems of tributary troughs hanging above major troughs, often with the development of rock basins. Ice cap or ice sheet development led to more complex systems of branching troughs, some formed by ice diffuent across a ridge from a valley with more ice to one with less (Linton, 1963). Ice streams further enlarged major troughs oriented in a direction permitting ice flow to lower or marine areas.

Further references can be found in Benn and Evans (2010), Evans (1997) and Glasser and Bennett (2004). Embleton (1972) and Evans (2008) discuss the older literature.

Glacial Cirques

Processes

Glacial cirques are concave landforms formed at the sources of mountain glaciers. They are doubly concave hollows, open downstream but bounded upstream by the convex crest of a steep headwall (Evans and Cox, 1974). The headwall is arcuate in plan around a more gently sloping floor that should show the effects of glacial erosion, if not buried under moraine and postglacial accumulations. The word is related to 'circus,' but

cirques must be open at one side. Their presence shows that a mountain range rose above the snowline long enough for small glaciers to form and to erode their beds. Cirques vary greatly in their degree of development, and it is useful to recognize five grades (Figure 1).

As rates of glacial erosion are believed to increase with basal shear stress or velocity, and thus with ice thickness and surface slope (Hallet et al., 1996), it may come as a surprise that such striking forms are produced at glacier sources, where discharge and basal velocity are low. The 'problem of cirque erosion' is to explain the concentration of erosion at the foot of the headwall. This is necessary to convert a nonglacial valley head into a cirque, and to produce a cliffed headwall. Periglacial and ice-marginal processes such as freeze-thaw cannot achieve this; they would cause retreat of the upper part, reducing headwall gradient.

Factors contributing to this explanation include duration of glacier cover, positive feedback on glacier balance, rotational flow and water pressure variations. As the snowline falls over a mountain range, the first glaciers will form in high cirques. And as glaciers waste away, those in sheltered, shady cirques are likely to survive the longest (Figure 2). The more deeply a cirque is eroded, the greater the shelter and (if pole facing) the shade provided, increasing the trapping of wind-blown snow and reducing the rate of melting. The increased mass balance gives a larger, thicker glacier, which may erode more effectively enlarging the cirque further and providing positive feedback. Extra input of snow at the top of a glacier, by wind drifting or avalanching, exaggerates the wedge of net accumulation and is effective in increasing velocity and tendency to rotate.

Cirque glaciers with gradients of roughly 10°–30° tend to flow in a rotational manner, as a wedge of net accumulation in the upper half flows to replace a wedge of net ablation in the lower. In warm-based ice, this maximizes basal sliding and concentrates erosion at the foot of the headwall, deepening the cirque floor and helping develop a closed basin (Lewis, 1960). This depends on ice thickness and surface gradient, and is not found in the Canadian glacier studied by Sanders et al. (2010). Many cirque glaciers are polythermal, and the

Figure 1 Cirques of different grades. (a) Bowscale Tarn, a classic (grade 1) cirque in the northern Lake District, England. The headwall consists of slates with varying degrees of metamorphism: the lake is up to 16.5 m deep. The unusually large moraine (bottom right) was produced by a Loch Lomond Stadial (Younger Dryas) glacier with an equilibrium line altitude (ELA) of about 536 m and a surface slope of 17°; it was up to 95 m thick. (b) Craig Trum y Ddysgl, the west side of a well-defined (grade 2) cirque in tuffaceous Ordovician sandstones above the Nantlle, North Wales. (c) Lonscale Cove, a definite (grade 3) cirque in slates east of Skiddaw in the northern Lake District, England. (d) Brown Cove Crags, a poor (grade 4) cirque in Ordovician volcanic rocks on the northwest slopes of Helvellyn, eastern Lake District, England. (e) Craig Rhiw-erch, a cirque in tuffaceous Ordovician siltstones, on Maesglase in the upper Dyfi basin, Mid Wales. It is marginal (grade 5) because of its steep (although drift-filled) floor (photographs by I.S. Evans).

Figure 2 Coalescent north-facing cirques with remnant Little Ice Age (LIA) glaciers at the head of Truax Creek, Bendor Range, British Columbia Coast Mountains. The three summits are at 2466, 2517 and 2589 m altitude: rocks are thermally metamorphosed mudrocks (photograph by I.S. Evans).

boundary between ice frozen to the bed and that which is sliding gives possible instabilities that facilitate quarrying (Richardson and Holmlund, 1996). This is most effective in sedimentary or well-jointed rock, in which thrust sheets may develop (Bennett et al., 1999). Continued erosion where ice is thickest, while peripheral ice is frozen to the headwall, may be a further factor undercutting the headwall. It is, however, limited to colder climates (continental and polar), as cold ice is not found near equilibrium line altitude (ELA) in snowy, maritime climates (see below).

Finally, the bergschrund and other crevasses formed as ice moves away from the headwall permit the periodic entry of meltwater. This causes variation in water pressure in subglacial pockets, facilitating the extension and opening of joints and the quarrying (plucking) of blocks of rock. This water pressure mechanism (Hooke, 1991; Iverson, 1991) has replaced Lewis' meltwater and freeze-thaw hypotheses, as temperatures beneath warm ice vary very little. Although abrasion is sensitive to basal velocity, quarrying is not so directly affected and is important on lee slopes under shallow ice flowing over bumps.

Rapid glacial erosion near the sources of mountain glaciers is thus explicable, and has the further effect of steepening the headwalls. This causes a threshold of stability to be exceeded, and the headwall retreats by episodic collapse in rock avalanches (Evans, 1997; McSaveney, 2002). These may occur when the glacier is active, but by removing support ('debudding' the slope) glacier recession makes them more likely. Again we note that frost action is not necessary; this is simply a slope stability problem, with slope gradient and height dependent on rock mass strength (RMS) (Augustinus, 1992). Figure 3 shows a cirque floor covered by two rock avalanche deposits, the results of headwall collapse in ultrabasic rocks. Headwall collapse is a normal part of cirque erosion, as basal glacial erosion steepens them beyond their maximum stable angle and height.

As many mountain areas have undergone tens of major glacial episodes in the Quaternary (and late Pliocene), considerable time is available for cirques to develop. Larsen and Mangerud (1981) studied deposits from a small cirque glacier on resistant mica-rich gneiss in western Norway. It eroded

Figure 3 Rock avalanche covering a cirque floor in the Shulaps Range, British Columbia Coast Mountains. The outer deposit (left) is covered by the 2500 BP. Bridge River Ash; the inner deposit is younger. The rock is serpentinised peridotite (harzburgite) (photograph by I.S. Evans).

118 000 m³ during 700 a of the Younger Dryas, equivalent to vertical lowering of the 0.21 km² cirque by 0.8 mm a⁻¹. At this modest rate, 200 m would be eroded in 250 ka of glaciation, which is sufficient to account for development of most cirques. Glaciation must, however, be of the appropriate style; ice should be wet-based, at least in part, and with steep surface gradients in cirques. The rapidity of climatic changes suggests that a prolonged phase of snowpatch activity (nivation) is unlikely before glaciers form. The nivation process-complex erodes more slowly than do warm-based glaciers; its importance has often been exaggerated, as has freeze-thaw action.

Distribution and Development

Spatially, glacial ELAs currently vary by 6000 m globally, by 600–2000 m between wet and dry sides of major mountain ranges, and by several hundred meters locally (Evans, 2006a). Glacial cirques likewise occur at lower altitudes on the snowy, windward sides of mid-latitude mountains. Globally, cirque floors are found down to an altitude below, and roughly paralleling, present ELA. As the zero (or other) isotherms follow a different pattern, both these observations relate cirques to glacial erosion rather than to frost action or any other factor directly related to atmospheric temperature. On a local scale, cirque glaciers and thus cirques favor shady and leeward slopes. In most areas they face poleward (Figure 4), and in the west-wind belt, their mean aspect is deflected toward the east, for example, in Europe, Tasmania, the Falklands, and the American Rockies. Thus, the distribution of cirques provides valuable evidence of former climates, including winds and sunniness as well as ELA (Mindrescu et al., 2010).

All of these spatial relationships lead to the rejection of a proposal by Turnbull and Davies (2006) that large cirques in general are formed essentially by deep-seated, often coseismic rock slope failures. The scars of such failures do indeed provide excellent locations for glacier initiation, but the distribution of such rock avalanche scars is very different from that of cirques, and sometimes complementary. The feasibility of mapping a 'paleo-glaciation level' separating mountains above, with cirques, from mountains below, without cirques, and the way its

Figure 4 Vector plots of cirque aspect. The resultant vector is in red, the individual aspects in blue, plotted in cumulated vector form. Scales vary. The Cayoosh Range, with a resultant a little east of north, is typical of fairly dry mountains of high relief, as in Central Asia and parts of British Columbia. The other three plots are all from the west-wind belt in Europe and show eastward tendencies as strong as northward, and stronger in Romania. Data for northern Scandinavia kindly supplied by S. Hassinen; for Romania, by M. Mindrescu (graphs by I.S. Evans).

altitude varies with precipitation, supports a strong climatic control. The relation of degree of cirque development to length and intensity of exposure to glaciations is also important.

Techniques for defining and measuring cirques are presented by [Evans and Cox \(1995\)](#) and, using Geographic Information Systems (GIS), by [Federici and Spagnolo \(2004\)](#). Where cirques are eroded into a plateau, their outlines are broadly rounded and the headwall crest approaches a semi-circular outline. Classically simple forms are found in horizontally bedded rocks such as basalts ([Figure 5](#)) or well-bedded sandstones. In sharp-crested mountains coalescence of cirques gives more angular outlines ([Figure 2](#)). Cirques are scale-specific forms, commonly between 200 m and 4 km wide and long, with the upper limit of width dictated by valley spacing. They are rarely over 2 km in Britain; larger cirques found in high-mountain areas tend to be complex, with smaller cirques nested within. Cirques around Mount Everest reach widths of 4 km, and some alpine valley heads in the Antarctic ([Haynes, 1998](#)) are over 8 km wide and long. These reflect much longer periods of alpine glaciation during the last 36 Ma. After deep glacial erosion, high-alpine cirque forms develop around trough heads ([Figure 6](#); see also [Figure 2](#) in [Evans, 1997](#)).

Cirque development involves flattening of the floor (eventually developing a reversed slope), steepening of the headwall, increased closure in plan as the headwall recedes more deeply

Figure 5 A trough-side cirque eroded into the basalt plateau above Isafjordur, northwest Iceland (photograph by D.J.A. Evans).

into the mountain mass, and increased length, width, and depth. As cirques develop, as expressed by their overall size, it appears that they increase in length faster than in width, and in depth least of all ([Evans, 2006b](#); [Federici and Spagnolo, 2004](#); [Gordon, 1977](#); [Figure 7](#)). Cirque development is thus allometric rather than isometric. For part of the Tien Shan, [Oskin and Burbank \(2005\)](#) have invoked cirque headwall

retreat two to three times faster than downward erosion. On the other hand, in the Ben Ohau Range, New Zealand, cirques seem to lengthen and deepen faster than they widen (Brook et al., 2006).

Haynes (1998) invoked long-term branching and coalescence keeping width and length in balance, so that alpine valley heads attain an equilibrium shape in plan: continual addition of new small cirques maintains positively skewed frequency distributions as older cirques widen and lengthen. Attainment of a steady state, however, requires downward erosion to match headwall retreat not only in cirques but in

their surroundings, including any glacial troughs below. This is possible only after cirque coalescence has eliminated gently-sloping higher surfaces, producing a landscape of arêtes and horns. Arêtes are sharp ridges produced initially between cirques side-by-side on the glacially favored side of a ridge. Those between cirques back-to-back are more likely to produce deep cols, but this requires glaciation that is more symmetrical between slopes of different aspects. Locally symmetrical glaciation (Evans, 2006a) is found either where ELA is well below ridge altitudes or where the climate is neither sunny nor very windy, and in theory it may permit steady state erosion once all headwalls are coalescent. In general, however, this situation has not been reached and the form of cirques changes (flattens) as they enlarge: they are not equilibrium forms. The factors discussed above permit quite rapid cirque erosion both downward and headward, and this is an important part of the 'glacial buzzsaw' (discussed below).

Figure 6 High-alpine cirques around a trough-head south of Tzoonie Mountain, 66 km NNW of Vancouver, British Columbia (photograph by I.S. Evans).

Glacial Troughs

Calibration

Popularly termed 'U-shaped valleys,' glacial troughs are the channels of present or former glaciers or ice streams. Like rivers, glaciers obey the necessary geometric relationship:

$$Q = Av \cong wdv$$

Discharge equals mean velocity (v) times cross-sectional area (A); the latter is approximately width (w) times depth (d).

Figure 7 Allometric plots of length, width and height (amplitude) against overall size, for cirques in Wales and the English Lake District (scales differ and are logarithmic). In both regions the gradient for amplitude is significantly less than those for length and width (graphs and data by I.S. Evans).

Figure 10 (a, b) Two views of the trough of Keary Creek, Bendor Range, British Columbia Coast Mountains. The foreground (of both photos) is on granodiorite; beyond the lake, the slopes are on thermally metamorphosed mudrocks. The upper slopes are gullied; talus covers those below a mid-slope trimline. These are typical trough sides: Keary Lake is a ribbon lake in a rock basin (photographs by I.S. Evans).

influenced by geology (e.g., joint spacing) and by the initial, preglacial profile. Initial variations in gradient are exaggerated by a positive feedback, basins are excavated in flatter sections, and the height of steps is increased. Steps are exaggerated because fluctuations in water pressure on lee slopes aid quarrying. Many steps (riegels, verrous) relate to zones of more resistant (usually less jointed) rock, but others relate to position within the system of glacial channels; as troughs tend

to be calibrated to ice discharge, steps are also expected at the confluences of major tributaries. Where the troughs are glacially calibrated, the degree of 'hang' relates to the difference in ice discharge: large tributaries hang less than small (Figure 13). This development of 'hanging valleys' has been simulated by MacGregor et al. (2000) (Figure 14). When simulating long profiles, erosion is proportional either to basal velocity or to its rate of change, depending whether erosion is 'production-limited' or 'transport-limited.'

MacGregor et al. (2009) simulated long profile erosion over 400 ka by a glacier some 20 km long, separating abrasion and quarrying in some runs. Abrasion was varied with clast concentration and angularity and with the square of basal sliding velocity. Quarrying was varied with bed gradient and sliding velocity. Long-term erosion lowered the glacier, reducing its mass balance and thus its length. The more realistic versions (with temperature varying over glacial cycles) did not develop closed basins in the upper reaches. Headwalls were not realistically steep, perhaps because frost action above the glacier was overemphasized compared with subglacial erosion by quarrying. The latter is essential to headwall development, but may be aided by rapid uplift (MacGregor et al., 2009).

Rock Basins and Fjords

The glacier bed can be irregular, with reversed slopes enclosing rock basins. The glacier surface must slope continuously down-valley to provide the necessary potential energy for flow (via shear stress). Of course, basins are found also in river beds, but on a much smaller scale. Glacier flow is approximately laminar whereas most rivers are turbulent; velocities are lower for glaciers than for rivers but pressures and stresses are higher. Glaciers are able to transport large blocks of rock up reversed bed slopes and are better placed than rivers to excavate fractured material from their beds: there is no limit to their competence.

There are three exceptions to the widely accepted view that glacial erosion is greatest around the EL. First, in multi-branched valley glacier systems, maximum discharge and erosion may be below confluences, some way below EL. Second, emergent flow in the lower ablation zone (to replace surface ice lost by melting, Figure 15) carries material upward and tends to excavate a rock basin near the terminus, so the lower ablation zone may be the locus of maximum erosion. This is most evident for tidewater glaciers (Figure 15), where flow (and basal velocity) accelerates toward the calving terminus and exceeds that at the EL. Third, under a polythermal ice sheet or ice cap, erosion is concentrated in warm-based areas with faster sliding: these are in the lower reaches of valleys, well below EL (Figure 6 in Jamieson et al., 2008).

Rock basins thus relate to position, and not only to lithology or structure. Rock basins are larger and deeper in the west of Scotland than in east, because of greater ice discharge due to heavier snowfall. Around the Alps it is notable how many deep lake basins lie just within the terminal moraines of major Pleistocene glaciers.

Modern seismic work on sediments in large lakes (mainly valley rock basins) has shown great thicknesses of glacial, glaciofluvial and postglacial sediment. The rock basins are

Figure 11 Fitting quadratic curves to a glacial trough cross-section. Each point plots the intersection of a contour with the profile. Note that an R^2 of 0.95 is obtained for a poor fit (top right), and even an R^2 of 0.97 (bottom two) does not guarantee a good fit, though 0.997 (top left) does. Quadratic curves are more robust than power curves (for which a complex iterative procedure is recommended) (graphs by I.S. Evans).

Figure 12 Long profiles of streams on the east slope of (a) the Sierra Nevada, California, and (b) the Sangre de Cristo Mountains, Colorado: no vertical exaggeration. These show the effects of glacial erosion in deepening and, especially, extending valleys, in areas of marginal glaciation (valley glaciers). Figure 13 On uniform granitic rocks, large tributaries of the Vénéon (Oisans, French Alps) hang less than small. Shaded bars are proportional to tributary catchment areas in km²; numbers below give step height in km. Step height also increases downstream as the trunk catchment area increases. Reproduced from Monjuvent G (1974) *Considérations sur le relief glaciaire a propos des Alpes de Dauphiné. Revue de Géographie Physique et de Géologie Dynamique, Série 2*, 16: 466–502.

Figure 14 Simulation of long profiles, with glaciers varying over the last 400 ka of environmental conditions and erosion proportional to basal sliding velocity. (a) Single glacier with no tributary; profiles at 40 ka intervals. INSET marine $\delta^{18}\text{O}$ curve used to simulate temperature. (b) Initial and final profiles with tributary joining at 10 km from sources, that is, equal to trunk; both 'hang' by 200 m. (c) Tributary at 20 km; a 100-m step is generated, with the tributary hanging by a further 100 m, and a shallow rock basin below. (d) Tributary at 30 km hangs by 200 m and trunk profile is little affected. (e) Long-term ice discharge (top line) and total erosion (bottom line) in trunk valley, for tributary at 20 km (solid lines) and for no tributary (dashed lines). Reproduced from MacGregor KR, Anderson RS, Anderson SP, and Waddington ED (2000) Numerical simulations of glacial-valley longitudinal profile evolution. *Geology* 28: 1031–1034.

Figure 15 Erosion of 'ablation area' rock basins; similarities and differences between land- and water-terminating glaciers, producing ribbon lakes and fjords, respectively. The upward flow tendency of a normal ablation area aids entrainment and excavation of a rock basin as the glacier thins toward the snout. This is enhanced in a tidewater glacier as it accelerates toward its calving front (sketch by I.S. Evans).

even deeper than formerly thought (often twice as deep as the water: [Figure 16](#)), and they are often dammed by massive rock thresholds, strengthening the case for glacial excavation. However, some of the deeper sediment is pre-last glaciation, showing that deepest excavation was by larger, earlier glaciers.

Fjords ([Figures 5 and 17](#)) are spectacular troughs, often with deep rock basins ([Holtedahl, 1967](#)), and shallow water near their mouths ([Figure 18](#)). Their thresholds are often where ice flow can diverge, at the edge of the mountains. Flotation and calving of ice reduce discharge more abruptly than does surface melting, and provide an extra explanation for the reversed slope. Never the less, in Scandinavia, British Columbia, Patagonia and New Zealand, the west coast fjords are almost matched by long ribbon lakes on the landward slope, often extending beyond the mountains: these must have formed largely under ablation zones, initially without calving.

Fjords are not tectonic landforms due to earth movements, but they may be structural landforms due to erosion exploiting fracture systems ([Figure 19](#); [Holtedahl, 1967](#)). Thus, fjords sometimes follow geological structures, but they often cut across contrasting rock types. On crystalline rocks around 72° N in East Greenland, ice-sheet erosion over the last 7 Ma deepened troughs and produced overdeepened basins and some interconnections, but the sinuosity of preglacial fluvial valleys was retained: low-gradient high areas eroded very little. On sedimentary rocks toward the coast, troughs were widened by ice streams and have smoother long profiles ([Swift et al., 2008](#)).

Classic fjords are transverse to coasts, but remarkable longitudinal fjords are found in southeast Alaska, British Columbia, and southern Chile. These reflect diffluent flow of ice, probably eroding lines of structural weakness. Longitudinal fjords may be characteristic of orogenic coasts (active

margins): they are largely absent from the passive margins around the North Atlantic.

Ages and Rates

Dating Forms

Some troughs appear to have developed solely by glacial erosion, but most have developed by the deepening and widening of preglacial valleys or graben. It is difficult to date large erosional forms, as most are modified over a series of glaciations. Allowing for duration, periods of greatest basal ice velocity will be most influential unless bedrock is protected by a cover of low-strength material. Discharge has varied greatly throughout the Quaternary, so the timing of formative discharge is an important question. Some troughs and basins, for example, around the periphery of the Alps, could develop only around times of glacial maxima. Others relate to intermediate, 'average Quaternary' conditions of much-repeated valley glaciation in mountains.

[Kleman et al. \(2008, Figure 9\)](#) mapped the durations of varying extents of ice, expected in Fennoscandia over the last 2.6 Ma. Interglacial conditions with glaciers in the mountains lasted 1050 ka, and mountain ice sheets (MIS, reaching no farther than the Gulf of Bothnia) lasted 1120 ka, much longer than the 440 ka of more extensive Fennoscandian Ice Sheets (FIS). The rock-basin ribbon lakes on the eastern side of the mountains could not have developed under FIS conditions, when they were near the main divide, with sluggish ice flow. They must have been eroded by MIS, which were especially important before 1 Ma ago. Similar conditions may apply in British Columbia (on the east side of the Coast Mountains, and

Figure 16 Cross-profiles of lake basins and sediments in the northwestern Alps (Switzerland and France). Basin depth is often twice water depth, as rapid sedimentation during deglaciation tends to fill the sediment trap formed by a lake. Coarse dots: glacially overridden deposits. the west side of the Columbia Mountains), but not in Patagonia or New Zealand where recent glacial maxima did not extend far beyond the ribbon lakes. Norwegian fjords could continue developing under both MIS and FIS conditions ([Kleman et al., 2008](#)), helping to explain their basins being deeper and their sides steeper than those of the ribbon lakes.

Full trough development requires erosion of 50–1000 m, which can be achieved at $0.1\text{--}2\text{ mm a}^{-1}$ for several hundred thousand years. These are the rates observed even for small

European glaciers in recent decades, as discussed below. Erosion is expected to be greater early in glacial epochs, as glaciers adjust the landscape to forms better adapted to ice discharge. But if ice becomes warm-based at a later stage, or more meltwater reaches the bed, erosion may accelerate late in glaciations, and abundant meltwater may evacuate stored sediment ([Koppes and Montgomery, 2009](#)).

If troughs are calibrated, are they equilibrium forms (unlike most cirques)? Once a well-calibrated trough has developed,

Figure 18 Long profile of Sognefjord (with its Lustrafjord source), western Norway. The level of hanging tributary fjord floors is shown by (Name. Profiles of summit levels on both sides are shown. The fjord floor is covered by an average thickness of 200 m of sediment. Reproduced from Nesje A and Whillans IM (1994) Erosion of Sognefjord, Norway. *Geomorphology* 9: 33–45.

Figure 19 Map showing the relation of fjords to the fracture system around Sognefjord, western Norway. Reproduced from Nesje A and Whillans IM (1994) Erosion of Sognefjord, Norway. *Geomorphology* 9: 33–45.

erosion may slow down and sediments may protect bedrock until greater ice discharges or velocities are achieved. Diminishing land-based glaciers require smaller A and v and are expected to be much less effective unless there is a change of thermal state, gradient or basal hydrology permitting more rapid sliding. Smaller, slower glaciers are likely to erode less bedrock, but abrading and quarrying (as well as slope collapse) do continue during deglaciation. Trough-widening is a one-way process, unlikely to be matched by downward erosion in a

steady state; the positive feedbacks involved make attainment of equilibrium unlikely.

Recent and Holocene Rates of Erosion

A consensus has emerged that wet-based mountain glaciers erode rapidly (Benn and Evans, 2010; Evans, 1997), especially in tectonically active areas, whereas completely cold-based glaciers are much less effective. Short-term (years or decades) measures of glacial erosion are based on suspended sediment concentrations in proglacial streams. Hallet et al. (1996, Table 1: see also Evans, 1997, Table 7.1) collated rates of $0.06\text{--}1.0\text{ mm a}^{-1}$ for small glaciers on crystalline rocks in Norway, $0.4\text{--}1.7\text{ mm a}^{-1}$ for small glaciers in Switzerland, $0.2\text{--}5.0\text{ mm a}^{-1}$ in central Asia (increasing with glacier size: Evans, 1997), and $5\text{--}60\text{ mm a}^{-1}$ for large tidewater glaciers in southeast Alaska. The latter estimates, however, are based on post-LIA (Little Ice Age) sediment volumes in fjords, accumulated during a period of rapid glacial recession associated with accelerated basal sliding. Koppes and Hallet (2006) conclude that longer-term (1000 years) rates are five times slower for the Muir Glacier and three times slower for the Tyndall. Making their proposed corrections, the Alaskan rates of $1\text{--}15\text{ mm a}^{-1}$ remain very high, yet are reasonable for an active orogenic area with high relief and high precipitation. They at least match rates of uplift and exhumation (Spotila et al., 2004).

Koppes et al. (2009) found a similar situation for a tidewater glacier in the Cordillera Darwin, Chilean Tierra del Fuego, which in 45 years has receded 13 km up a fjord and is now 21 km long. Glaciér Marinelli has eroded an average of 39 mm a^{-1} of bedrock over this time, but for stable conditions a rate of 10 mm a^{-1} is extrapolated, and it should be noted that the recession phase of fjord glaciers is much shorter than the advancing phase. As corrected, Hallet et al.'s (1996) data show very high erosion rates in glacier basins larger than 200 km^2 , and rather lower rates for those below 60 km^2 . On a broader scale, Sheaf et al. (2003) calculated the volume of Holocene sediment offshore from the $47\,500 \text{ km}^2$ Pacific drainage of the St. Elias Range, inferring accelerated denudation of at least 5.1 mm a^{-1} over 10 000 a.

The Norwegian glaciers have been more stable during the period of sediment measurement: Nigardsbreen has eroded at an average rate of 0.15 mm a^{-1} for 25 years, a period long enough to smooth out interannual variations in sediment evacuation by subglacial streams. Bedrock erosion is expected to be proportional to the rate of basal sliding, but Riihimäki et al. (2005) show that even a low rate of sliding ($1\text{--}2 \text{ m a}^{-1}$) can erode $1\text{--}2 \text{ mm a}^{-1}$ beneath a small valley glacier.

Areas with more sluggish throughput of snow and ice, such as the dry end of the Pyrenees, have lower erosion rates. Delmas et al. (2009) demonstrated temporal and spatial variations in glacial and paraglacial erosion, with more erosion during deglaciation due to supplies of supraglacial debris, and with cirque headwall recession faster than overall averaged denudation.

Longer-Term Late Cenozoic Exhumation

Over a longer term, rates of surface denudation generally increased in the Late Cenozoic, at times of inception or extension of glaciation. Berger et al. (2008) found that denudation and exhumation of the windward (ocean) side of the St. Elias orogen (southeast Alaska) accelerated around 1 Ma ago, from 0.3 to 3 or 4 mm a^{-1} . They attributed this to the more extensive glaciation (greater ice discharge and near-total cover to the edge of the continental shelf, during maxima) following the mid-Pleistocene transition from dominantly 40 to 100 ka glacial cycles. Glaciation has affected orographic kinematics, producing a narrowing of the orogenic wedge; although the St. Elias may be extreme in both tectonic activity and intensity of glaciation, similar changes are expected in other orogenic belts (Berger et al., 2008). Southeast Alaska is one of several regions where broad glacial troughs ('sea valleys') cross the continental shelf, as recognized off Labrador long ago by F. P. Shepard (Evans, 2008).

Similarly in British Columbia, Shuster et al. (2005) found a sixfold increase in erosion around 1.8 Ma, deepening the Klinaklini trough by 2 km. Although the Klinaklini discharged ice from the interior of British Columbia, this glacial acceleration of erosion was widespread in the southern Coast Mountains (Ehlers et al., 2006). The Late Cenozoic increase in denudation rates, especially 2–4 Ma ago, was global. It is attributed partly to expanded glaciations and to lowered sea level exposing continental shelves, but also to the increased amplitude and frequency of environmental change, preventing the establishment of equilibrium states (Peizhen et al., 2001).

Long-Term Rates: Landform Evidence

In terms of landform development, the overall rate of denudation is less important than the spatial pattern. The more selective, concentrated impacts of glacial erosion, compared with the even surface lowering in mature fluvial landscapes (Jamieson et al., 2008) explains the dominance of glacial forms in glaciated mountains. This provides strong evidence of the effectiveness of glacial erosion: the distinctive landforms of glaciated mountains have survived over 11 000 years of fluvial and slope processes. Small glaciers are often concentrated on one side of a ridge, either the shadier or the sheltered side (Evans, 2006a). This leads to cirque headwall retreat: Evans (2006b) cited examples where headward erosion around north-facing glacier sources has pushed divides southward, for example, by 1 or 2 km in parts of the British Columbia Coast Mountains. Brocklehurst and Whipple (2006) suggested that cirque headwall retreat is important on the east slope of the Californian Sierra Nevada, causing divide recession of up to 2.5 km beyond that expected from fluvial erosion (Figure 12).

Oskin and Burbank (2005) proposed that as mountains are uplifted above the snowline, glacial erosion increases local relief by deepening and widening fluvial valleys. In the Kyrgyz Range of the Tien Shan this starts from the north slope, where the snowline is some 200 m lower, and the divide is pushed 0.9–4.4 km southward. Erosion is localized at the bases of cirque headwalls, and cirque headwall retreat is two to three times the rate of vertical erosion. "Cirque retreat can effectively bevel across an elevated alpine plateau..." (Oskin and Burbank, 2005, p. 936).

In 11 east-trending valleys in the Bitterroot Mountains of Idaho, north-facing glaciers have deepened tributary valleys by 90 m more than fluvial erosion on south-facing slopes, and headwall retreat has pushed divides on average 400 m southward (Naylor and Gabet, 2007). Amerson et al. (2008) showed that in both central Idaho and the Olympic Mountains, for a given drainage area and comparable lithology, glaciated valleys are around 32% deeper than fluvial valleys, and around 37% wider. On the granitic rocks of central Idaho, overall valley-side slope gradients exceed 35° only in glaciated valleys. Although Koppes and Montgomery (2009) find that river incision in active orogens can be as fast as glacial denudation, the above results are evidence of glacial erosion exceeding fluvial during the Late Quaternary.

In Norway and British Columbia, great contrasts in precipitation between coastal and inland areas have affected the degree of glacial activity. Rudberg (1997) made estimates of the volume of rock removed to produce various landforms in central Norway, comparing the $15\,100 \text{ km}^2$ coastal province of Møre og Romsdal with an adjacent comparable area inland:

Volume in km^3 :	Coastal	Interior
V-shaped fluvial valleys	15	22
Cirques	60	4
Trough valleys	2150	330
Fjords/lakes	1290	4
Sounds and submarine valleys	265	
Strandflat	270	

Although very rough, these estimates clearly show the much more intense glacial transformation of the land surface in the

coastal area, of the order of tenfold. This is attributed to high snowfall producing faster flow and greater erosion in the windward, coastal area.

Landscapes of Glacial Erosion

Buzzsaw Hypothesis

Based on this demonstration that glacial denudation is more effective than fluvial (so long as glaciers are wet-based), and a second assumption that basal sliding and thus erosion are greatest around the ELA, recent papers have likened glacial erosion to a buzzsaw (chain saw) operating at ELA, and near-truncating mountain ranges so that only a small proportion of mountain area rises above ELA. While noting that recent sediment yields in southeast Alaska have accelerated, [Spotila et al. \(2004\)](#) found that spatial patterns of denudation over the long term (million years) are strongly correlated with the distribution of glaciers, and the southward decrease in ELA correlates with a decrease in mean elevation. [Berger and Spotila \(2008\)](#) found that exhumation over the last half million years peaks at some 4 mm a^{-1} , between the intersections of the present and the Last Glacial Maximum (LGM) ELAs with the topography of the Chugach–St. Elias Range. Exhumation does not vary laterally with glacier size, implying that erosion by both larger and smaller valley glaciers has kept pace with Late Quaternary rock uplift. [Enkelmann et al. \(2009\)](#) related the very young rock cooling ages around the Seward–Malaspina glacier system to intense localized exhumation at an active orogenic ‘corner’: rapid glacial erosion is coupled with active tectonic uplift.

In part of the Washington Cascades, [Mitchell and Montgomery \(2006\)](#) noted a parallelism between three trends: nonvolcano summit altitudes, cirque floors, and modern glacier median altitudes. Each rises eastward at $9\text{--}15 \text{ m km}^{-1}$. Only about 10% of each section rises above the highest cirque floors, and few peaks rise more than 600 m above. Rock exhumation rates are greatest 30–40 km west of the highest peaks, and suggest vertical erosion of 2–5 km in the last 15 Ma. This is not the pattern expected from fluvial or slope erosion, so Mitchell and Montgomery proposed a glacial buzzsaw of greatest glacial erosion at the average Quaternary ELA (represented by the cirque floors), where ice discharge and velocity were greatest. This increased the slope gradients above cirque floors to over 30° , causing slope failure. Thus, both vertical and headward erosion in cirques is considered to dominate landscape development at high altitudes.

Recent work has used hypsometric (area-altitude) analysis to support the Buzzsaw Hypothesis. The most ambitious was by [Egholm et al. \(2009\)](#) and [Pedersen et al. \(2010\)](#), using SRTM data for most of the world (up to 60°N and 55°S). For 1029 one-degree data tiles with mountains believed to rise above present ELA, they establish a pronounced maximum of area some 660 m below present ELA. This applies across a broad range of ELAs, from 1000 to 6000 m. It is supported by a series of minima in average slope gradient, between present ELA and 1000 m lower. In that range, (tangent) gradients average 0.27–0.29, whereas they soon rise to 0.32–0.42 on either side (Figure 4A in [Pedersen et al., 2010](#)). Where good ELA data were available from the World Glacier Inventory, clear area maxima were 600 m below present ELA in Tibet

(with the Himalayas and Tien Shan), 700 m below in southern Norway, 850 m in Mongolia and southwest Siberia, and 1050 m in coastal Alaska and B.C. Area maxima for individual data tiles are mainly between present and former (Late Quaternary) ELAs. Only in a few regions do peaks rise more than 1500 m above present ELA (Figure 2 in [Egholm et al., 2009](#)). [Egholm et al.](#) were also able to model the development of the hypsometric maxima.

Van der Beek and Bourbon (2008) analyzed the hypsometry and clinometry of part of the Dauphiné Alps, France, and confirmed a strong glacial imprint. For seven major drainage basins, area peaks at altitudes between present (2900 m) and glacial maximum (1800 m) ELA: 61% of the area of the nine basins studied lies within this band, which is 41% of the total altitude range. In the most heavily glaciated basins (the Upper Romanche, Séveraisse, and Vénéon), this is accompanied by a shallow minimum in mean slope gradient.

The positional and lithological reasons for some peaks rising hundreds of meters above the rest were discussed by [Foster et al. \(2010\)](#) for the Teton Range of Wyoming, where headward erosion is important and the Buzzsaw Hypothesis is otherwise applicable. They did, however, suggest a discharge threshold: glaciers with basins over 20 km^2 incise much deeper troughs than smaller glaciers. Small glaciers ($<10 \text{ km}$ long at maximum), in several Idaho ranges uplifting at 0.3 mm a^{-1} or less, have eroded effectively and limited maximum altitudes, which trend parallel to cirque floor altitudes and to estimates of LGM ELA ([Foster et al., 2008](#)). There are some hypsometric maxima near LGM ELA, and steeper gradients above, also supporting the Buzzsaw Hypothesis. Small glaciers in the Teton Range were apparently less effective in eroding the highest summits, perhaps because the Range is rising at a fast rate of 2 mm a^{-1} ([Foster et al., 2008](#)).

Simulations by [Anderson et al. \(2006\)](#) confirmed that valley glacier erosion should be greatest near the long-term mean ELA, so long as this is below the summits and the ice is warm-based. They proposed a more robust rule, that erosion peaks at 30–40% of the distance from source to maximum glacial limit (if within a valley). Note also the three situations discussed above where valley glacier erosion may reach a maximum well below ELA, and that on a low-gradient glacier the ELA erosion maximum is broad, due to discharge initially rising and falling slowly either side of EL. [MacGregor et al.’s \(2009\)](#) simulation of cirque development produced cirque floors hundreds of meters below ELA.

The Buzzsaw Hypothesis can explain why so many mountain ranges have small glaciers, while very few have extensive icecaps or icefields; outside polar regions, the latter are confined to Patagonia, the Saint Elias and the Karakoram. Each of these appears to be undergoing rapid uplift, sufficient perhaps to take substantial areas quickly through the zone of varying ELA to altitudes where ice is cold-based and less erosive. The glacial buzzsaw limits peak altitudes in many glacially dissected regions (with intersecting cirque headwalls). That cannot apply where smooth summit surfaces are only partly consumed by cirque development, as in the Colorado Rockies (Front Range) but, even there, hypsometric maxima may relate to cirque floors. Together with the asymmetric divides discussed in the previous section, such evidence confirms the effectiveness of glacial erosion in many mountain ranges.

Figure 20 Selective linear erosion of troughs requires basal ice at pressure melting point, in a depression that can channel ice flow. Reproduced from Sugden DE (1974) Landscapes of glacial erosion in Greenland and their relationship to ice, topographic and bedrock conditions. In: Brown EH and Waters RS (eds.) *Progress in Geomorphology*. Institute of British Geographers Special Publication 7: 177–195.

Selectivity

Sugden (1974) noted the importance of relief and basal temperature in developing different landscapes of glacial erosion. Where ice had remained frozen to its bed, there was hardly any erosion unless meltwater from upstream froze on to the glacier base. Where deeper valleys had permitted basal melting and thus sliding, they were deepened further while intervening uplands were unaffected (Figure 20). Valleys focusing ice flow and facilitating evacuation to areas of net ablation permitted faster flow and generation of more heat and more basal melting; positive feedback enhanced the landscape contrasts. Where a whole landscape was covered by warm-based ice, it was scoured into rocky hills and lake basins. These three landscape types were labeled, respectively, landscapes of no erosion; of selective linear erosion; and of areal scouring. They contrast also with a fourth, alpine landscape, of cirques and troughs.

Kleman and Stroeven (1997) demonstrated the selectivity of glacial erosion in the Swedish mountains, and Kleman et al. (2008) applied the concept throughout the FIS area. Recent studies using terrestrial cosmogenic nuclide (TCN) concentrations confirm the selectivity of glacial erosion. For example, from striated surfaces near the downstream ends of two glacial troughs, some 2.5 m has been eroded during the last major

Figure 21 NASA Landsat image of Canadian Shield around the eastern arm of Great Slave Lake, Canada. Cuestas in the Lake show differential glacial erosion among bedded volcanic rocks. Elsewhere the pattern of small lakes shows erosion of thousands of rock basins in Precambrian (Archaean) igneous and metamorphic rocks by the Laurentide Ice Sheet.

glaciation near the trough center, declining to lesser depths near the margins (Fabel et al., 2004), as predicted by Harbor's model. This study was based on abraded areas, not quarried. Further upstream, the depth of scour was greater, with complete removal of inherited nuclides throughout the cross-section. TCN work in Labrador also confirms selectivity of erosion (Staiger et al., 2005); summit plateaus where ice has always been cold have been lowered <3 m over 20 glacial cycles, whereas valleys with wet-based ice have been lowered at least 50 m by glacial erosion. Delmas et al. (2009) find limited and selective glacial erosion at the drier, eastern end of the Pyrenees.

Thus, many recent studies, including Swift et al. (2008), have confirmed the applicability of Sugden's model to landscape development on tectonic passive margins around the North Atlantic. Erosion on these margins is also much slower than in high-precipitation orogenic areas such as southeast Alaska, Patagonia and much of the Himalaya.

Areal Scouring

Landscapes of areal scouring might be expected to show streamlining and, thus, lineation. This is common on weak rocks, for example, around the Forth in central Scotland (Linton, 1963). On resistant metamorphic and igneous rocks of the Canadian and Fennoscandian Shields, there is strong structural control of glacial erosion with lake basins along fault and major joint lines, and on weaker rocks (Figure 21). This leads some to infer that glaciation has simply removed a mantle of weathered rocks, which is clearly the case in some marginal areas of decelerating flow. Elsewhere, in the absence of deeply weathered material, erosion of bedrock may have been considerable but is difficult to measure. Kleman et al. (2008) suggested that

ice-scoured areas developed quickly, under rapid ice flow toward calving margins: some could develop only under more extensive, FIS conditions.

Micro- to Macroscale Forms

B R Rea, University of Aberdeen, Aberdeen, UK

© 2013 Elsevier B.V. All rights reserved.

Micro- to macroscale forms of glacial erosion represent some of the most widely recognized indicators of glaciation and pay testament to the efficacy of glaciers as erosional agents (Figure 1). The use of micro- to macroscale forms of glacial erosion was vital in the evolution of Quaternary science with regard to the development of the 'glacial theory' in the mid-1800s and the wide acceptance that significant areas of the mid-latitudes supported extensive glaciers and ice sheets in the past (Agassiz, 1831; Forbes, 1843).

The suite of features produced by glacial erosion, from micro- through macroscale dimensions, forms a continuum shown in Table 1. In relation to Quaternary science, these erosional forms play a number of roles. Their presence in the landscape provides unequivocal evidence of former glaciation and that the ice was, at least at some time, warm-based (Benn and Evans, 1998). All ice-streamlined erosional forms can be used to identify ice-flow directions, but must be interpreted in conjunction with other information (e.g., topography, erratic trains, and paleogeography) as many are bidirectional indicators of ice flow (Table 1). The ultimate goal is to link erosional forms with ice dynamics in order to facilitate detailed reconstructions of former ice masses. The first requirement, however, is to understand the processes of subglacial erosion.

Fundamentals of Glacial Erosion

The first and most fundamental consideration related to all the landforms detailed in Table 1 is that they are only produced by ice that is warm-based/wet-based/at the pressure melting point and sliding across its bed (Benn and Evans, 1998). Although there are reports of basal sliding at subpressure melting point temperatures, the amount of erosion that may be accomplished is likely to be minimal. All the forms discussed here are eroded in bedrock and are only produced where there is 'direct' (cavities included) contact between the ice and the bed or there is a thin (probably discontinuous) sediment layer between the bedrock and the glacier sole. Two processes of glacial erosion are responsible for the formation of all the forms listed in Table 1, abrasion and quarrying (Boulton, 1974). The erosion of bedrock by flowing subglacial water (mechanical and/or chemical) is not considered explicitly here, although it may play some part in the formation of a number of the landforms described. Subglacial bedrock erosion rates by abrasion and quarrying are generally assumed to be dominant over subglacial fluvial processes.

Abrasion

Abrasion is the process of (frictional) wear, produced by surfaces rubbing against each other, and is achieved in the subglacial environment by sliding of debris-charged ice across the bed. The key is the presence of debris (clasts) in the basal ice of

the glacier. Ice-on-rock will not produce mechanical wear of the bed, although it may produce chemical erosion through dissolution. Rather, it is at the contact between clasts entrained in the basal ice and the bedrock where abrasion/wear occurs. The classic illustration of subglacial abrasive wear are striae (Figures 1 and 2), which are ubiquitous on bedrock that has been overridden by debris-charged warm-based ice. Chamberlin (1888) undertook the first and most comprehensive field investigation, providing very detailed descriptions of striae and friction cracks.

Careful observations of striae provide key indicators of the formation process. The sides of striae are often jagged and rough, with partial ring fractures present in the bottom that are most often concave in the direction of flow (Figure 3). This demonstrates that the plowing of the asperity (a point protuberance from a clast that contacts the bed) into the bed proceeds by brittle fracture. The stress fields created beneath static and sliding contacts are well known from fracture and rock mechanics, and they provide a complete explanation of striae formation (Frank and Lawn, 1967; Lawn, 1967; Swain and Lawn, 1976). A brief description is provided here, and a more detailed explanation can be found in Iverson (1995). Figure 4 shows the bed stresses and likely crack paths developed beneath static spherical, static point, and sliding spherical asperities, associated with a loading-unloading cycle. The important points to note are the ring, central, and median crack paths and, when sliding, how the stress trajectories are modified such that partial ring fracture formation is most likely at the trailing edge contact. Close observation of striae in the field often reveals the presence of partial ring fractures (Figure 3). Figure 5 presents an experimental striation indicating how the trailing edge tensile stresses and crack paths are controlled by contact geometry. Here the contact was oriented oblique to movement with cracks becoming curved (concave down-ice) laterally beyond the trailing edge contact (Figure 4(c)). Figure 6 shows the relationship between contact geometry and stress in the bed for plowing asperities (Iverson, 1991a). The expected crack paths are at the trailing edge of the contact for low plowing angles (similar to the sliding spherical indenter in Figure 4(c)) but extend into and ahead of a high plowing angle contact. Thus, for high plowing angles the asperity is more likely to plow down into the bed (Figure 6(c)). Parameters that potentially control striae formation (abrasion) are the force pressing the asperity against the bed (F_n), the hardness of the clast relative to the bed, the geometry of the asperity-bed contact, and the relative velocity of clast to ice.

Over the length scales of striae, $\leq 1\text{--}2\text{ m}$ (Table 1), none of these parameters are likely to change significantly except the contact geometry (Iverson, 1991a, 1995), and this is the primary control on striae morphology. F_n is a critical parameter and there is divergence of opinion regarding the contributing factors. Boulton (1974) suggested that it is a function of the effective pressure acting on the bed. Problematic with this

theory is that at high effective stress, clasts are prone to lodgement (increased bed friction), and therefore there is difficulty explaining the formation of valleys and fjords that contained thick ice masses. Hallet (1979, 1981) argued that the Boulton model could not promote the deviatoric stress required to induce bed fracture because the same stress is transmitted to the bed via the ice-bed or basal water-bed contact. Hallet proposed that F_n is the sum of the buoyant weight of the clast and the viscous drag imparted on the clast by the component of ice flow that is directed toward the bed, and it is essentially independent of the ice thickness. In his model, thin, warm, fast sliding ice is the most erosive. Hindmarsh (1996) argued that the presence of discontinuities in meltwater film pressures developed around clast edges can isolate cavities around clasts by effectively pinching out/pressure sealing them from the wider basal hydraulic system. The cavity size is controlled by the relative velocity of the clast and the ice and the effective pressure in the cavity. As the cavity grows, the ratio of horizontal to vertical forces acting on the clast increases and motion may be permitted. F_n is then related to the relative velocity of clast to the ice through the water pressure gradient on the stoss side of the clast. Cohen et al. (2005) demonstrated, from subglacial experiments in the Engabreen subglacial laboratory,

that the simple friction law implied by the Boulton model could not account for the high shear tractions (100–500 kPa) they measured, but their results did demonstrate a dependence of shear traction on effective normal stress. Their data failed to demonstrate a clear dependence of shear traction on melt rate,

indicating that the Hallet model did not correctly account for F_n either. Using their empirical data they developed a model where F_n is a function of both the effective normal stress (Boulton) and the viscous drag from ice flow toward the bed, but differed in its parameterization of this from the Hallet model. Modeling results suggested that a limited particle size range, 0.007–0.1 m, contributed approximately 90% of the bed friction and that sufficiently large and small (<200 μm) particles tended to become lodged. The lodgement of large clasts may well have implications for the formation of friction cracks and p-forms (see below).

Abrasive wear, through indentation fracture and plowing, is responsible for all bedrock streamlining by mechanical subglacial erosion, and thus contributes to the formation of all the streamlined forms described below.

Quarrying

The effects of abrasion can best be viewed by looking in the direction of ice flow to see the characteristic smoothed bed (Figure 2), whereas the effects of quarrying are best seen looking in the opposite direction, upflow (Figure 7). Quarrying is generally accepted as a two-component system comprising fracture (breakdown of intact rock) and plucking/entrainment (removal) (Boulton, 1974; Iverson, 1995).

Fracture

Fractured lee sides of bedrock protuberances are, in many instances, controlled by preexisting joint systems (Matthes, 1930;

Figure 5 Experimental striation showing how the geometry of the clast–bed contact controls the trailing edge stress pattern and thus the crack geometry. The oblique-to-flow clast–bed contact produced similar oriented cracks, which become concave downflow (like a partial ring fracture) beyond the contact. Photograph by B. R. Rea.

(c) A large type 1 striation containing multiple crescentic gouges (contained within the striation margins – dashed line) along its length. Ice flow was from left to right, the striation is ~ 0.9 m long, 0.15 m wide (max.) and 0.009 m deep (max.). Photograph by B. R. Rea.

Figure 7 The effects of the abrasion and quarrying are more clearly evident when looking in down- and upflow directions, respectively. This view is looking upflow showing clearly the 'rough' appearance in this direction. The stoss-lee forms, resulting from structural control and subglacial erosion, are clearly evident. Ice-flow direction is indicated by the white arrow. The smoothing effect of abrasion is clearly seen in the downflow direction as shown in Figure 2 (the look direction is oblique to ice flow across the rock step with the white arrow). Photograph by B. R. Rea.

Rastas and Seppälä, 1981). Subaerial weathering, either chemical or mechanical, undoubtedly presents a rockhead of open joints and fractures that are easily plucked from the bed. Once these have been removed, further bed erosion proceeds by quarrying of more resistant bedrock. It occurs in massive bedrock (Gordon, 1981; Figure 8) and lodged boulders (Boulton,

Figure 8 Massive bedrock showing the effects of quarrying. The fracture bears no relation to any obvious preexisting or inherent bedrock structure. Reproduced from Gordon JE (1981) Ice-scoured topography and its relationships to bedrock structure and ice movement in parts of northern Scotland and West Greenland. *Geografiska Annaler* 63(A): 55–65, with permission.

1974), indicating that the process may be effective even in the absence of joints and bedding planes. Controlling factors in the process are the bed roughness, the presence of subglacial cavities and water pressure fluctuations within them and inherent flaws and microcracks in the bedrock or boulder. A brief discussion is provided here, and the reader is directed to Iverson (1995) and Hallet (1996) for further details. Iverson

Figure 9 The importance of the stoss-lee form and related water-filled cavity in controlling bed stresses. Cracks are likely to develop parallel to the contours of greatest principal stress (dashed lines), maintaining the stoss-lee form. Rapid drainage of the cavity increases pressure on the bed and may enhance rates of crack growth. Modified from Iverson NR (1991) Potential effects of subglacial water-pressure fluctuations on quarrying. *Journal of Glaciology* 37: 27–36.

(1991b) demonstrated the role of cavities in enhancing stress in the bed and highlighted the potential role of water pressure fluctuations in promoting bedrock fracture. Figure 9 illustrates the projected principal stress directions (and likely crack trajectories) created by a water-filled lee side cavity. Although the stresses calculated by Iverson (1991b) were unlikely to induce critical (instantaneous propagation) crack growth, subcritical (slow propagation) crack growth was likely. Rapid water pressure reductions result in significant increases in the mean bed pressure, thereby increasing the tendency for bed failure. Fracture potential is further enhanced for water-filled cracks as water pressure within them is less responsive than in the cavity (Iverson, 1991b, 1995). Subcritical crack growth is fundamental to the process because it allows bed fracture (quarrying) to proceed under stresses that do not exceed the tensile strength (fracture toughness) of the bedrock (Atkinson, 1982). Loading must be sufficient so that stresses are raised above a minimum threshold, and given this condition and sufficient loading time, subcritical crack growth should result in bed failure. Hallet (1996) investigated the stress state in a series of rock steps superimposed on a horizontal bed (Figure 10) under varying levels of ice–bed separation (i.e., cavity length). As ice–bed separation increases, so does the normal stress supported across the contact areas. More important for bed fracture, tensile stresses are developed in the bed just upglacier from the point of cavity closure, and these drive crack growth and fracture. Note that the stoss-lee form is self-reinforcing in that fractures are likely to grow subvertically down into the bed, maintaining the stepped appearance as the lee faces migrate upflow.

Plucking/Entrainment

For completion of the quarrying process, loose material has to be removed from the bed. This requires displacement of the material from *in situ*, which is easiest for very loose material that can be removed by bulldozing and overriding during the initial ice advance. Robin's (1976) heat pump effect provides a mechanism to 'freeze on' the glacier sole to the bed, but the low shear strength of this bond makes it unlikely that such a

Figure 10 A horizontal bed comprising a series of rock steps with cavities developed in the lee-side. Bed stresses are elevated at the areas of ice–bed contact, and tensile stresses are developed in the bed, just upflow from the closure of each cavity. Reproduced from Hallet B (1996) Glacial quarrying: A simple theoretical model. *Annals of Glaciology* 22: 1–8, with permission of the International Glaciological Society.

mechanism will produce significant amounts of plucking alone. The hydraulic jacking effect of Röthlisberger and Iken (1981) integrates the heat pump concept with water pressure fluctuations in subglacial cavities. Upglacier from the cavity, as water pressure falls, so ice pressure increases. This increased pressure may lead to the expulsion of intercrystalline and regelation meltwater from basal ice and the ice–bed interface. Subsequently, with a rise in cavity water pressure, the mean ice pressure on the bed is reduced (i.e., the water supports more of the ice overburden), raising the pressure melting point, resulting in refreezing of available meltwater. If the expelled water cannot be replaced, for example, from an adjoining cavity, heat conduction from the bedrock leads to freezing on. With the hydraulic jack, ice–bed adhesion occurs under reduced effective stress which should be more effective than the heat pump effect alone (i.e., reduced effective stress reduces friction along bedrock joints and fractures; Iverson, 1995). The only other method for removing material is through the viscous drag induced by ice flow over the bed, which increases with the upglacier dip of the stoss surfaces and ice velocity. However, the joint shear strength (the force resisting removal) also increases with these factors. Rea and Whalley (1996) showed that drag-induced removal of joint-bounded blocks was possible from steeply upglacier dipping bedrock steps in air-filled cavities under thin ice (Figure 11(a) and 11(b)). The squeezing of ice along the lateral and rear bounding joints of the blocks (Figure 11(c)) reduced joint friction and assisted block removal. Sediment injection into bedrock joints and fractures has also been proposed, which would facilitate, in an analogous manner, the plucking of bedrock beneath thin and patchy till cover.

It is generally accepted that quarrying is volumetrically of greater significance than abrasion in terms of total glacial erosion (Iverson, 1995), with abrasion never exceeding 40% of the total erosion (Hallet, 1996). Quarrying is the only source of new abrasive beneath glaciers and ice sheets once preexisting regolith has been removed.

Figure 11 (a) Active quarrying of a block (left side of image) from the lee-side of a roche moutonnée. (b) A lee-side view of a roche moutonnée looking upflow. Note the space at the ice–bed separation point where a joint-controlled block has recently been removed (above 75-cm-long ice axe). (c) Squeezing of ice around a joint-controlled block at the crest of a roche moutonnée. This reduces friction along the joints, facilitating plucking. Glacial Erosional Forms

Striae

In accordance with the first descriptions of these forms by Chamberlin (1888), types 1–3 are used throughout the remainder of this article as descriptors of striae morphology (Figure 12(a)). The abrupt end to type 1 striae results from the asperity either breaking off or rotating completely out of

the striation due to increased coupling (shear stress supported) across the clast–bed contact (Figures 6(c) and 12(b)). If, instead of asperity fracture or complete outrotation, the plowing angle decreases due to gradual clast rotation and/or wear of the asperity, the striation will gradually shallow with displacement (following indentation and plowing – type 1), forming a type 2 striation (Figure 3). Type 3 striae are formed by static indentation followed by plowing with a reducing plowing angle (i.e., the second part of a type 2 striation; Figure 12(c)).

Friction Cracks

These are a family of forms that tend to be found on horizontal to upglacier dipping, smoothed abraded bedrock surfaces and include crescentic fractures, lunate fractures, crescentic gouges, and conchoidal fractures (Figure 13(a)). Crescentic fractures (Figure 13(a)(i) and 13(b)) tend to form en echelon, sometimes with decreasing or increasing diameter in the ice-flow direction. These are most easily explained as partial ring fractures formed at the trailing edge contact of a rounded (low plowing angle) sliding asperity (Figure 4(c)). Lunate fractures (Figure 13(a)(ii) and 13(c)) and crescentic gouges (Figure 13(a)(iii) and 13(c)) are assumed to be formed by a similar process, with the differing orientation of the horns resulting from the clast–bed contact geometry. Common to both forms is a shallow down ice-dipping principal fracture (Figure 13(a)(ii,iii)) and intersecting secondary fracture defining the wedge of rock removed. Iverson (1991a) suggested that the primary fracture could form ahead of a plowing asperity (Figure 6(b)), in a manner similar to a Riedel (R)-type shear produced along shearing fault surfaces. The only shallow outward dipping fractures that form beneath asperities are either the lateral crack formed during unloading beneath a static contact (Figure 4) or fractures formed ahead of a steep plowing contact (Figure 6(b)). The geometry of lunate fractures and crescentic gouges allow some conclusions to be drawn regarding their formation. The primary fracture of the lunate fracture has a shallow dip in the direction of ice flow from a concave downflow contact, which is most easily interpreted as a rounded trailing edge contact. The primary crack must then have formed below the asperity–bed contact, analogous to an R-type shear, with the secondary crack forming subsequently as a partial ring fracture under a static or sliding contact beneath the same asperity. The primary fracture of the crescentic gouge has a shallow dip in the direction of ice flow (Figure 13(a)(iii)), from a convex downflow leading edge contact, indicating that it formed ahead of the asperity–bed contact. This could represent either an R-type shear produced ahead of a steep plowing contact (Iverson, 1991a) or a lateral crack produced beyond the contact area of a blunt static contact. The secondary fracture results from either the termination of the asperity plowing (i.e., the crescentic gouge represents a very short type 1 striation) or a partial ring fracture developed under static loading, beneath the same blunt asperity. Experimental evidence of brittle fracture in glass suggests that the orientation may have some relation to the dynamics of the contact (i.e., sliding may produce concave and convex downflow forms, whereas rotating contacts produce only concave downflow forms; Smith, 1984). Conchoidal fractures are

Figure 12 Examples of typical glacial striae. (a) The striae type classification based on the descriptions of Chamberlin (1888). reported less often in the literature but are likely to originate close to the slope break, which they cross-cut, in a manner similar to a lunate fracture.

p-Forms

Dahl (1965) introduced the term plastically molded forms to describe a range of smoothed bedrock erosional features, including transverse, longitudinal, and nondirectional forms. A number of processes have in the past been suggested for the origin of p-forms, but only two are currently advocated. One theory favors a subglacial fluvial origin, with the striae that cover their surface representing a minor 'ornamentation' component in their formation (Kor et al., 1991). The alternative theory views some p-forms as undoubtedly of a subglacial fluvial origin (e.g., potholes), with others resulting from quarrying and abrasion, perhaps with additional fluvial erosion (Boulton, 1974; Goldthwait, 1979; Rea et al., 2000). The quarrying and abrasion origin only is of relevance to this article. Boulton (1974) suggested that streaming of ice around bed obstacles focuses erosion along and downstream of the flanks of the obstacle (Figure 14(a)), leading to the formation of sichelwannen, which could be especially effective in the lee side of smaller bed obstacles (Iverson, 1995). Alternatively, following the modeling of Cohen et al. (2005), large boulders will tend to lodge on the bed and streaming around the flanks of the contact, in a manner similar to that envisaged by Boulton (1974), could, produce a sichelwannen or muschelbruch form. Goldthwait (1979) cited convergent striae into deep limestone grooves and the lack of percussion marks (fluvial) on Kelleys Island, Lake Erie, as evidence for formation by ice abrasion. Rea et al. (2000) presented detailed observations of contemporaneous subglacial multidirectional ice flow and linked these to proglacial bedrock striation patterns, indicating how glacial erosion can exploit preexisting bedrock joint patterns to produce transverse troughs (Figure 14(b)), furrows, and comma forms (Figure 14(c)). It seems that there are some p-forms which are undoubtedly of subglacial fluvial origin, but many others are of a subglacial mechanical origin or polygenetic with a minor to significant input from both processes.

Polish

Table 1 indicates that striae are formed at the centimeter to meter scale, although this is not strictly true because they are found down to the micrometer scale. This small-scale abrasive wear produces a 'polished' appearance to freshly exposed bedrock. The polish may be developed on the bedrock by the gradual smoothing by shearing of clasts and fines (sand and silt) across the bed (without significant indentation/plowing) or within the finer-grained material (rock flour) undergoing shear between clast-bed (Figure 15) and ice-bed contacts (Lee and Rutter, 2004; Rea, 1996). The polish will be short lived if it is developed in the rock floor or longer lived if it is developed on the bedrock. Exposure to subaerial weathering will gradually roughen the surface.

Roches Moutonnées

Roches moutonnées are the classic example of subglacial bedrock erosion, with abrasion dominating on the upstream (stoss) side and quarrying producing the (sub)vertical lee side (Figure 11(b)). The component of ice flow toward the bed is greatest approximately half way up the stoss side (Iverson, 1995), enhancing clast-bed contact stresses and favoring the

Figure 13 (a) Morphology of friction cracks, comprising (i) crescentic fractures, (ii) lunate fractures, (iii) crescentic gouges, and (iv) conchoidal fractures (p, primary crack and s, secondary crack). (b) A series of crescentic fractures on quartzite bedrock (some are highlighted by dashed lines) where ice flow was from right to left. (c) Exposure showing multiple crescentic gouges and one lunate fracture (arrowed) where ice flow was approximately top left to mid right. Photographs by B. R. Rea.

production of deep striae (Rastas and Seppälä, 1981). Bed-normal stresses are lower along the flanks and so striae should be shallower (Rastas and Seppälä, 1981). Bedrock jointing often controls the orientation of the lee sides (Matthes, 1930; Rastas and Seppälä, 1981; Rea et al., 2000). Above however, it has been shown that the presence of the (sub)vertical lee sides focus bed stresses, facilitating quarrying even in the absence of preexisting joints (Figures 9 and 10). Friction cracks are more frequently found toward the top of roches moutonnées (Rastas and Seppälä, 1981). This may seem counterintuitive because F_n is highest halfway up the stoss sides; however, the largest clasts are likely to make contact only with the tops of roches

moutonnées (Iverson, 1995) due to the shadowing effect of successive roche moutonnée (rock steps; Figure 10). As indicated in Table 1, roches moutonnées (including flyggbergs, which are large-scale asymmetrical hills) cover a large range of scales, such that smaller roches moutonnées may be superimposed on the stoss sides of larger ones.

Whalebacks and Rock Drumlins

If bedrock quarrying is suppressed and abrasion still occurs, elongate and smoothed bedrock protuberances may be produced. Where the form is asymmetric with a steeper stoss side

Figure 14 (a) Bedrock protuberance with evidence for enhanced erosion along the flanks as proposed by Boulton (1974; note penknife for scale). Photographs by B. R. Rea. (b) Joint-controlled channel (containing conforming striae) on a stoss surface. Photograph by B.R. Rea. (c) A comma p-form with conformable striae. (b) and (c) Reproduced from Rea BR, Evans DJA, Dixon TS, and Whalley WB (2000) Contemporaneous, localized, basal ice-flow variations: Implications for bedrock erosion and the origin of p-forms. *Journal of Glaciology* 46: 470–476, with permission of the International Glaciological Society.

(like a drumlin), it is known as a rock drumlin (Figure 16(a)), and the more symmetrical forms are known as whalebacks (Figure 16(b)). The suppression of quarrying is likely linked to the absence of lee side cavities, intransient basal water pressures, and mechanically strong, massive bedrock (Evans, 1996; Gordon, 1981). High effective stresses (thick ice and low basal

Figure 15 Polish developed between a shearing clast and the bed in the bottom of an experimental striation. Note the striated surface of the polish and the granular composition below (right side of micrograph). Micrograph by B. R. Rea.

water pressures) and low sliding velocities suppress ice–bed separation; thus, quarrying by either of the mechanisms discussed previously (Figures 9 and 10) is unlikely. It has been suggested that whalebacks are best developed beneath thick fast-flowing topographically controlled ice streams so that ice–bed separation is suppressed (Evans, 1996; Roberts and Long, 2005).

Crag and Tail

As indicated in Table 1, crag and tails cover a significant scale range and are represented in microforms as mini crag and tails. At all scales, they comprise a resistant core forming the steep stoss side, with an elongate tail formed in the lee (Figure 17(a)). The classic example is in Edinburgh, UK, with Edinburgh Castle built on the crag and the Royal Mile being the tail (Benn and Evans, 1998). The crag is a volcanic plug and the tail comprises less resistant sedimentary rocks so that the tail is protected in the lee of the resistant plug in a direction paralleling the direction of former ice flow. In many instances, the tail is composed of unlithified sediments, deposited in the lee of the crag, so strictly speaking, these are not true erosional forms.

At a smaller scale, changes in bedrock structure or composition may produce a protective crag. At the miniscale, resistant inclusions such as chert nodules in carbonate rocks (Figure 17(b)) form the crag and there are often troughs cut into the bed around the crag, making a sickle-shaped depression. In less well-developed situations, this is likely to resemble a sichelwannen.

Applications in Quaternary Science

All of the forms described previously provide unequivocal evidence for the presence of former warm-based glaciers and ice sheets. All of the forms associated with abrasive wear indicate that the ice contained debris in traction across the bed. Roches moutonnées and crag and tail provide clear unidirectional ice-flow evidence, whereas other streamlined

Figure 16 (a) Rock drumlin that has undergone subsequent lee-side quarrying. The original surface is shown as a dashed white line. Ice flow was from right to left. Photograph by B. R. Rea. (b) Whaleback from the southern edge of Jakobshavns Isfjord, west Greenland. Ice flow is from right to left. Photograph by D. H. Roberts.

forms provide equivocal or bidirectional ice-flow directions (i.e., may be streamlined by ice flow from one of two directions) and require additional information (e.g., erratic trains) to define absolutely the former ice-flow direction. Crossing striae (or striae directions) are regularly observed in the field and require careful interpretation (Figure 18). In some instances, they represent contemporaneous ice flow (Rea et al., 2000), and in others they represent changing dynamics and flow directions within a single or multiple glaciations. If cross-cutting relationships can be defined at the outcrop scale it may be possible to determine a relative chronology (Figure 18). It has been suggested, for example, if fine striae are found cross-cutting deeper striae, then the deeper striae are older (Sharp et al., 1989), but this only holds if the fine striae can be traced across the base of larger striae. However, if only multiple direction relationships are recorded on a bedrock surface, care must be taken. For example, if the direction of fine striae on the lee sides of a roche moutonnée are at odds with the direction of stoss side striae, they are not necessarily of a different age. The fine striae may be older having been preserved/protected in the lee sides of the roche moutonnée, or they are synchronous and represent contemporaneous

multidirectional ice flow (Rea et al., 2000). The primary fracture in lunate fractures and crescentic gouges (Figure 13(a)(ii, iii) and 13(c-e)) invariably dips in the direction of ice flow and so may be used to reconstruct former ice-flow directions. Wintges (1985) performed a photogrammetric survey of friction cracks, differentiating populations formed under multiple phases of glaciation. A most interesting result was an apparent nonlinear dependence of crack size on ice thickness. Presumably, this is at least partially due to its contribution to the effective pressure, but components of the ice dynamics, such as basal melt rate will also contribute to F_n (Cohen et al., 2005), which is the major control on their formation. The origin of p-forms is still disputed, and linkages with ice dynamics, beyond the ice being warm based, have yet to be made.

The presence/absence or juxtaposition of roches moutonnées and whalebacks provide a potentially fruitful line of inquiry for determining, at least at a broad scale, the dynamics of former ice masses. Evans (1996) and Roberts and Long (2005) suggest that high effective pressures developed beneath thick, topographically confined, 'ice streams' led to cavity suppression, prohibiting quarrying and allowing abrasion to dominate. Cavity suppression will undoubtedly limit quarrying, however, for

Figure 17 (a) Generalized configuration of a crag and tail. The simple requirement is a harder crag forming the stoss end and less resistant surrounding rock forming the tail. (b) Mini crag and tails (rat tails) formed by the protection of weaker dolomite in the lee of chert nodules. Reproduced from Prest VK (1983) Canada's Heritage of Glacial Features. Miscellaneous Report No. 28. Vancouver: Geological Survey of Canada, with permission of the Geological Survey of Canada.

Figure 18 (a) Bedrock exposure showing three generations of striae. Detailed inspection of the striae relationship at the outcrop scale failed to yield conclusive evidence for their age relationship. However, based on an interpretation of increasing topographic control during deglaciation the chronology is 1 (oldest) through 3 (youngest). (b) The large deep striation (parallel to the knife) appears to cross-cut the top right-bottom left trending striae, but again proving a cross-cutting relationship from the outcrop alone is nontrivial. Photographs by B. R. Rea.

abrasion to occur there still needs to be sufficient force pressing clasts against the bed in the lee side of the whaleback. This is somewhat problematic for the 'symmetry' of whalebacks as ice flow is directed away from the bed in the lee side which will reduce all components contributing to F_n so the abrasion rate should be lower in the lee than on the stoss. Therefore, it is theoretically difficult to have high rates of lee side abrasion, but in order for a symmetrical whaleback to form, stoss and lee side abrasion rates must be comparable, or the form is an inherited landform, which seems unlikely. As ice thins during deglaciation, effective pressures become transient and quarrying may proceed, producing superimposed roches moutonnées (Roberts and Long 2005).

It is through the use of combined data sets that the best reconstructions of former ice dynamics are made. An excellent example is that of Sharp et al. (1989), who integrated detailed bedrock erosional information, including striae directions and depths, frequency and orientation of quarried faces, ice thickness estimates, rock fracture relationships, and glaciological theory, to interpret the dynamics and erosional styles beneath ice filling Llyn Llydaw, North Wales, during the late Devensian glaciation (ice sheet) and the Loch Lomond Stadial (Younger Dryas; valley glacier) glaciation.

Further advancement in our understanding of subglacial erosional process will undoubtedly lead to the use of micro- to macroscale forms of glacial erosion to allow more rigorous and

quantitative reconstructions of the dynamics of former glaciation. A better understanding of the formation/evolution of whalebacks in particular, probably holds important information regarding the dynamics of former ice streams and the dichotomy of apparent fast ice flow with an absence of lee side ice-bed separation and equity of stoss and lee side abrasion rates.

Paleoenvironmental records reveal the climate of the past 2 million years to be characterized by large-scale oscillations in global temperature. Short periods of relative warmth (interglacials, which last for several thousand years) are separated by lengthy periods of cooling (glacial periods, which last for several tens of thousands of years) followed by rapid warming and then return to an interglacial state. The records also show that global ice volume, sea level, and atmospheric composition are intrinsically linked with these temperature changes (Petit et al., 1999). The climate oscillations have three distinct frequencies, which relate strongly to cyclical variations in Earth's orbit around the Sun (as predicted by Croll in the nineteenth century and later refined by Milankovitch in the twentieth century). This association has led to a consensus among glaciologists that ice ages (i.e., the growth and decay of ice sheets) are forced by orbital variations. The consequence of this view is that significant modification to Earth's climate results from external influences, and that such influences are inevitable in the future. However, because the percentage changes in solar inputs resulting from orbital variations are low, it is unreasonable to expect that orbital variations alone can explain the growth and decay of huge Quaternary ice sheets. In other words, solar forcing of ice sheet behavior needs to be amplified. Such amplification is thought to result from a number of 'feedback' systems operating among a variety of Earth surface (or near surface) processes (Figure 1). Comprehension of glacial feedback mechanisms requires a holistic appreciation of these processes and their interaction.

The last glacial cycle is characterized by a general increase in global ice volume from the Eemian interglacial ~125 ka, when sea level was ~3 m higher than at present and there was less ice in the world than today, to the Last Glacial Maximum (LGM) ~21 ka years ago (Figure 2), when sea level was 120 m lower. In between, there were several global ice volume peaks, corresponding to solar insolation minima. By the early

Holocene, ~8 ka, the distribution of ice about Earth was fairly similar to today, with the notable exception of the West Antarctic Ice Sheet, which took until the mid-Holocene to retreat to its current position.

Glacier Mass Balance, Equilibrium Line Altitudes, and the Growth and Decay of Terrestrial Ice Sheets

Ice sheets build mass through several accumulation processes (Paterson, 1994; Figure 3). In maritime climates, direct snowfall contributes the bulk of accumulation. In polar desert environments, on the other hand, accumulation can be restricted to the freezing of condensation precipitated from air on the ice surface (Rignot and Thomas, 2002). After a number of years (several tens of years at the center of large ice sheets), the surface material is compressed and turned to glacial ice. Ice accumulates across the highest, coldest regions of an ice mass, known as the accumulation zone, and is lost at the lower, warmer end of the ice mass within the ablation zone. If an ice mass terminates in water, ice can also be lost from marine melting (at the ice margin if grounded, or under the ice if floating) and iceberg calving. The line between the ablation and accumulation zones is called the equilibrium line, and its elevation is referred to as the equilibrium line altitude (ELA). The position of the ELA dictates the size of the accumulation and ablation zones. The process of ice flow acts to transfer mass from the accumulation zone into the ablation zone. An ice mass is said to be 'in balance' when the volume of ice accumulated equals the volume ablated and the volume transferred beneath the ELA. In this condition, in which the ice mass remains stable, neither growing nor shrinking, the ELA is at a position that allows this 'steady state' to exist. If accumulation exceeds ablation, then the mass balance will be positive and the glacier will grow. On the other hand, if the ablation is larger

Figure 1 Feedback processes involved in the growth and decay of ice sheets: thermohaline circulation feedbacks, ice sheet surface albedo feedbacks, marine ice sheet and sea-level feedbacks, and ice sheet elevation feedbacks.

than accumulation, the mass balance becomes negative and ice recession occurs. Generally, ice accumulates in the winter and ablates in the summer. In most cases, when glacier mass balance is positive, the summer melt season is cooler, and the ELA is lower. Conversely, warmer summer conditions increase the ELA, resulting in more melting, and if this continues for several years, the ice mass terminus will retreat to high elevation. This simple relation between summer air temperature and mass balance holds as much for large terrestrial ice sheets such as in Greenland as it does for small valley glaciers.

For nonglaciated terrain to become covered with ice, the ELA needs to be lower than the highest topography. This can best be achieved by reducing summer temperatures, thus allowing cirque and small mountain glaciers to form in the first instance. As the ELA is lowered further, the size of the ice masses may increase, and glaciers may merge as single large ice bodies. In this way, large terrestrial ice sheets may be established. Higher summer air temperatures will act to raise the ELA, resulting in increased ablation and ice retreat. Thus, the growth and decay of ice sheets on land can be related to the position of the ELA and, consequently, to summer temperatures.

Because orbital forcing of solar radiation changes is too small to account solely for the growth of continental ice sheets at the LGM, other mechanisms that amplify the solar effects on air temperature are required.

Sea Level and the Growth and Decay of Marine-Based Ice Sheets

Reductions in ELAs may allow ice from land to flow to the sea. Once at the coast, ice flow into the sea will be curtailed by iceberg calving and melting at the ice–water interface. The formation of marine-based ice masses (e.g., the West Antarctic

Ice Sheet) is thought to be assisted by sea-level fall in two ways (Siebert, 2001). First, as a result of sea-level lowering, the shallowest regions of continental seas may become subaerially exposed, after which terrestrial ice sheet formation may take place. Second, as modern glaciers terminating and grounded in water experience loss of ice from iceberg calving at a rate linked to the water depth, sea-level fall may result in a reduction in the rate of iceberg calving of such glaciers and, hence, their growth into formerly deeper water. Sea-level reduction during an Ice Age is caused by an increase in the global ice volume (i.e., the transfer of water from oceans to the continent). Lowering sea level causes marine ice sheets to grow, which results in further reduction in sea level (although marine ice sheets displace part of their weight in water, and so their effect on sea level is less than that of ice sheets on land). A simple positive feedback process is thus defined by which ice growth may result in further growth. Since it is not likely that marine ice sheets can initiate sea-level fall, their growth must be a consequence of the expansion of terrestrial ice masses.

During deglaciation, however, marine ice sheets may experience decay at least in part because of sea-level rise for two reasons. First, as sea levels increase, so too may the rates of calving at grounded ice margins. Second, increasing sea levels result in decreasing friction at the base of marine ice sheets and, hence, enhanced flow of ice to the margin. Another feedback is thus established in which sea-level rise leads to marine ice sheet decay and, in turn, further sea-level rise.

A classic example of how the growth and decay of marine ice sheets are influenced by sea-level changes is the late Weichselian Eurasian ice sheet, which at its maximum occupied the whole of the Barents Sea. During ice sheet growth between 30 ka and the LGM, ice flowed from land masses such as Svalbard and Scandinavia into the shallowing continental seas, forming a large continuous ice mass across the Eurasian Arctic.

Figure 2 Ice sheets of the Last Glacial Maximum. Note that the size of the Eurasian Ice Sheet across northern Europe and Arctic Russia is shown in both maximum (after the CLIMAP project of the 1970s) and minimum (after the QUEEN project of the 1990s) configurations. The locations of the Antarctic, Greenland, Laurentide, Cordilleran, Eurasian, Patagonian, and New Zealand ice sheets are provided. Adapted from Broecker WS and Denton GH (1990) The role of ocean–atmosphere reorganisations in glacial cycles. *Quaternary Science Reviews* 9: 305–341.

Deglaciation occurred first within the deepest marine sections of the ice sheet soon after the LGM, and the ice front quickly migrated back to the coastal regions, thus rapidly deglaciating the Barents Sea. Numerical modeling results of the growth and decay of the Eurasian ice sheet are provided in [Figure 4](#).

Surface Albedo, Solar Radiation Budget, and Ice Sheet Fluctuations

The albedo of a surface is a measure of its reflectivity to solar radiation ([Paterson, 1994](#)). If the albedo of a surface is high,

Figure 3 (Top) Ice sheet and (bottom) glacier, mass balance, and flow.

more radiation will be reflected than if the albedo is low. Hence, the average albedo of the planet dictates the levels of solar radiation held and reflected at its surface. Fresh snow has a particularly high albedo. This reflective property results in amplification of the solar forcing of air temperature. As snow fields and ice sheets expand as a result of a reduction in the solar insolation-induced air temperature, the surface albedo will be increased, and the net amount of solar radiation held by the Earth will be reduced. Air temperature will be reduced further, resulting in glacial expansion. At the LGM, when large sections of the Northern Hemisphere were permanently covered with snow and ice, the surface albedo of the planet, and therefore the level of radiation retained, was significantly different from that of today (~ 0.22 compared to ~ 0.14 ; D. Lunt, personal communication). Therefore, through adjustment to the Earth's albedo, ice sheets contributed to global cooling and, hence, their own existence.

Conversely, during deglaciation, this feedback system works to accelerate ice sheet decay. When air temperatures increase and snow and ice melt, the reflectivity of the Earth's surface decreases and, hence, solar radiation is retained. The increase in net radiation leads to increased temperatures and to more ice sheet decay, further lowering the albedo.

Atmospheric Carbon Dioxide Levels and Ice Sheet Changes

Atmospheric carbon dioxide (CO_2) has an impact on climate because it absorbs/reflects longwave radiation emitted from the Earth's surface (i.e., the greenhouse effect). As air bubbles trapped in the ancient ice of deep ice cores demonstrate, when the air gets colder, atmospheric CO_2 is depleted. As the atmosphere cools in summers at the beginning of a glacial cycle (due to solar insolation changes), the CO_2 level drops and, as a result, so too does the absorption of longwave radiation. Hence, heat is lost from the Earth, yielding further cooling. During deglaciation, warmer temperatures are associated with increased levels of atmospheric CO_2 and an enhanced 'greenhouse' effect.

Figure 4 Growth and decay of ice in the Eurasian Arctic during the late Weichselian, as calculated by a numerical ice sheet model (Siegert and Dowdeswell, 2002; Siegert et al., 1999). Maps show the thickness of ice at the following times: (a) 30 ka, (b) 25 ka, (c) 20 ka, (d) 15 ka, (e) 14 ka, (f) 13 ka, (g) 12 ka, and (h) 11 ka. Contours are given in meters.
